This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

Methods of Bain and Pacini . 1

EXCISION OF BONES AND JOINTS, by T. HOLMES, Esq., revised by JOHN H. PACKARD, M.D.

PAGE

EXCISIONS IN GENERAL:

General Indications for Excision, as preferable—

1. To the Expectant Treatment 198
2. To Amputation . . . 199
  As regards the Seat of Disease 199
  As regards the State of the Patient 200
  As regards the Character of the Disease . . . 200
  As regards other Circumstances 201
General Observations on Operations of Excision . . . 201
  Instruments needed or useful . 202
Subperiosteal Excision . . 204

EXCISIONS IN PARTICULAR:

Excision of the Shoulder . . 205
Excision of the Scapula and Clavicle 208
Excision of the Elbow . . . 210
Excision of the Wrist . . . 214
Excision of single Bones of the Hand 216
Excision of the Hip . . . 216
  For Injury 219
Excision of the Knee . . . 222
Excision of the Ankle . . . 230
Excision of the Bones of the Foot 234
Excision of the Os Calcis . . 235
Excision of the Astragalus . . 236
Total or Partial Resections of Long Bones 237
Subperiosteal Excision of the Shafts of Long Bones . . 237

DISEASES OF THE JOINTS, by ATHOL A. JOHNSTONE, Esq., revised by E. H. BRADFORD, M.D.

PART I. DISEASES COMMON TO ALL THE JOINTS:

General Considerations . . 240
Diseases of Synovial Membranes 240
  Synovitis 240
    Varieties 241
Simple Acute Synovitis . . 241
  Acute Articular Abscess . 242
Chronic Synovitis . . . 243
Treatment of Acute Synovitis . 244
Incision and Drainage of Joints 245
Treatment of Subacute and Chronic Synovitis . . . 246
Dropsy of Joints . . . 247
Scrofulous Synovitis; Pulpy Degeneration 249
  Symptoms 250
  Treatment 252
Rheumatic Synovitis . . 253
Chronic Osteo-Arthritis; Chronic Rheumatic Arthritis; Rheumatic Gout 253
Gouty Synovitis 257
Pyæmic Synovitis . . . 259
Gonorrhœal Synovitis; Gonorrhœal Rheumatism . 260
Syphilitic Synovitis . . 260
Loose Cartilage in Joints . . 261

DISEASES OF THE ARTICULAR EXTREMITIES OF THE BONES:

Simple Inflammation and its Consequences . . . 263
Scrofulous Inflammation . . 264
  Prognosis 266
  Treatment 267
Rheumatic and Syphilitic Inflammation 269
Rachitic Affections of the Articular Ends of Bones . . 269
Tumors of the Articular Ends of Bones 269

ABNORMAL CONDITIONS OF THE ARTICULAR CARTILAGES:

Anatomy and Physiology of Articular Cartilage . . . 270
Hypertrophy 271
Atrophy 271
Gouty Deposits . . . 271
Fatty Degeneration . . . 271
Ossification 271
Ulceration 271
[AFFECTIONS OF THE JOINTS SECONDARY TO CHANGES IN THE SPINAL CORD . . . . 274]

DISEASES OF OTHER TISSUES IN AND AROUND THE JOINTS:

Diseases affecting the Ligamentous Structures . . . 274
Diseases affecting the Muscles . 276
Diseases affecting the Areolar and Adipose Tissues . . 277
Diseases of the Synovial Bursæ 277
Altered Conditions of the Integuments around the Joints 277

ANKYLOSIS:

False Ankylosis . . . 278
  Treatment 279
Osseous Ankylosis . . . 280
ARTICULAR NEURALGIA . . 281
INJURIES OF JOINTS . . . 282

PART II. DISEASES OF INDIVIDUAL JOINTS:

Diseases of the Hip . . . 286
  Acute Arthritis . . . 286

PAGE
Common Synovitis . . . 286
Morbus Coxarius; Strumous Synovitis and Osteitis . 286
Symptoms 286
Diagnosis 289
Treatment 290
Morbus Coxæ Senilis . . 291
Diseases of the Pubic, Sacro-Iliac, and Sacro-Coccygeal Joints 292
Diagnosis of Sacro-Iliac Disease 293
Diseases of the Knee . . 294
Chronic Osteo-Arthritis . 294
Inflammation of Bursæ near the Knee 294
PAGE
Wounds of the Knee-Joint . 295
Diseases of the Ankle . . 295
Diseases of the other Articulations of the Foot . . 295
Inflammation of the Scapho-Cuneiform Joint . . 296
Diseases of the Sterno-Clavicular, Acromio-Clavicular, and Sternal Joints . . . 297
Diseases of the Shoulder-Joint . 297
Diseases of the Elbow-Joint . 298
Diseases of the Wrist and other Articulations of the Hand . 299
Diseases of the Temporo-Maxillary Articulation . . . 299

DISEASES OF THE SPINE, by Alex. Shaw, Esq., revised by E. H. Bradford, M.D.

Caries of the Spine 300
Symptoms of Incipient Stage . 301
Rigidity of affected portion . . 302
Heat and Swelling . . . 302
Pain 303
Diagnosis from Neuralgia of the Spine 303
Angular Deformity 304
Changes in Chest and Abdomen . 306
Spinal Abscess 306
Ankylosis 307
Spurious Ankylosis . . . 308
Importance of distinguishing these 308
Psoas and Lumbar Abscess . . 309
Psoas Abscess 309
"Neck" of the Abscess . . 310
Lumbar Abscess 310
Spinal Abscess in the Neck . . 311
Varieties in Spinal Abscesses . . 311
Diagnosis of Spinal Abscess . 312
Treatment of External Spinal Abscesses . . . 313
Affection of the Spinal Cord from extension of the Disease . 315
Disorganization of the Cord; Paraplegia 316
Spasmodic actions of the Paralyzed Limbs 317
Diagnosis 317
Prognosis in Paraplegia . . 317
Treatment of Spinal Disease . . 320
Prone-Couch 321
Counter-Irritants . . . 321
Disease of the Atlas and Axis . 322
Symptoms 324
Prognosis 325
Treatment 325
Necrosis of the Atlas . . 326

ORTHOPÆDIC SURGERY, by W. J. Little, M.D., revised by E. H. Bradford, M.D.

Webbed Fingers 326
Pathology of Deformities . . 327
[Paralytic Disorders of Childhood . . . . . . 329]
Secondary Changes . . . 330
Congenital Club-Foot (Talipes Varus Congenitus) 330

Knock-Knee 361
  Treatment 362
[Curvature of Bone . . . . . 364]
Orthopædic Operations applicable to the removal of Curvature of the Bones 365
Ankylosis of the Knee and other Articulations . . . 367
  Classification of Cases . . 367
  Treatment by Gradual Extension 369
  Division of Hamstring Muscles 371
  Forcible Subcutaneous Separation of the Femur and Tibia in Bony Ankylosis of the Knee
  Division of Muscles in the vicinity of the Hip-Joint . .
  Division of Flexor Tendons of Fingers and Toes . . .
  [Section of the Bones . .
  Forcible Extension . . .
    Under Chloroform . .
[Addenda:
  Inequality in the Length of the Lower Limbs . . . .
  Osteitis Deformans . . .
  Deformity from union of Fractures in a faulty Position . .

AFFECTIONS OF THE MUSCULAR SYSTEM, by T. Tatum, Esq., J. Lockhart Clarke, Esq., M.D., F.R.S., revised by P. S. Conner, M.I

Affections of Muscles:

Strains and Contusions . . 378
Rupture of Muscles . . . 378
Inflammation of Muscles . . 380
  As a symptom of Syphilis . 380
Simple Contraction of Muscles from Syphilis 381
[Syphilitic Affections of Muscles 382]
Muscular Atrophy . . . 382
  1. Simple Atrophy . . . 382
  2. Granular Degeneration . 383
  3. Fatty Degeneration . . 383
  4. Waxy or Vitreous Degeneration 383
  Pathology of Muscular Atrophy 384
  Etiology 384
  Treatment 384
Atrophy from Infantile Paralysis 385
Degeneration of Muscles with apparent Hypertrophy . . 385
  Morbid Anatomy and Treatment 386
Ossification of Muscle . . .
  [Forms of this Affection . .
Tumors in Muscles . . .
  Fibrous Tumors . . .
  Cysts (Trichinous, etc.) . .
  Vascular Tumors . . .
  Cancer of Muscle . . .

Affections of Tendons:

Injuries of Tendons . . .
Inflammation of Tendons . .
  Whitlow . . . . .
  Treatment . . . . .
Syphilitic Enlargements of Tendons . . . . .
Tumors of Tendons . .

Affections of Bursæ Mucosæ:

Enlarged Bursæ . . . . .
"Housemaid's Knee" . . . .
Bursal Abscess . . . .
  Treatment . . . .
Enlarged Bursæ of Tendons .
  Treatment . . . .

PART III.

DISEASES OF THE NERVOUS SYSTEM.

DISEASES AND INJURIES OF NERVES, by J. Lockhart Clarke, M and C. E. Brown-Séquard, M.D., revised by Roberts Bartholow, A. M.D., LL.D.

Part I. Nerve-Lesions and their More Immediate Effects. By J. Lockhart Clarke, M.D.:

Diseases of Nerves . . . 401
Inflammation of Nerves . . 401
  Acute Neuritis . . . 401
  Chronic Neuritis . . . 402
  Idiopathic Neuritis . . . 403
  Traumatic Neuritis . . . 404
Ulceration of Nerves . . . 404
Tumors of Nerves . . .
  Painful Subcutaneous Tubercle
  Neuroma . . . .
    Varieties . . . .
  Tubercle and Cancer . .
Hypertrophy and Atrophy of Nerves
Injuries of Nerves . . .
  Contusions . . . . .
  Compression and Distension .
  Laceration of Nerves . .
  Ligature of Nerves . .

LIST OF ENGLISH CONTRIBUTORS TO VOL. III.

A. W. Barclay, M.D.; Physician to St. George's Hospital.

Arthur E. Durham, Esq.; Assistant-Surgeon to Guy's Hospital.

Holmes Coote, Esq.; Surgeon to St. Bartholomew's Hospital.

George Harley, M.D., F.R.S.; Physician to University College Hospital.

T. Holmes, Esq.; Surgeon to St. George's Hospital.

Athol A. Johnstone, Esq.; Late Surgeon to the Hospital for Sick Children.

Alexander Shaw, Esq.; Consulting Surgeon to the Middlesex Hospital.

W. J. Little, Esq., M.D.

T. Tatum, M.D.

J. Lockhart Clarke, Esq., M.D., F.R.S.

C. E. Brown-Séquard, M.D., F.R.S.

Thomas Longmore, Esq.; Deputy Inspector-General of Hospitals, Professor of Military Surgery at the Army Medical School, Netley.

Joseph Lister, Esq., F.R.S.; Professor of Clinical Surgery at King's College Hospital.

Thomas Smith, Esq.; Surgeon to the Hospital for Sick Children, and Assistant-Surgeon to St. Bartholomew's Hospital.

J. Birkett, Esq.; Surgeon to Guy's Hospital.

B. E. Brodhurst, Esq.; Orthopædic Surgeon to St. George's Hospital.

G. Busk, Esq., F.R.S.; Surgeon to the Dreadnought Hospital Ship.

Sir J. Ranald Martin, C.B., F.R.S.; Examining Medical Officer to the Secretary of State for India in Council.

LIST OF AMERICAN REVISERS OF VOL. III.

J. Solis Cohen, M.D.; Lecturer on Laryngoscopy and Diseases of the Throat and Chest, Jefferson Medical College; Physician to Jefferson College Hospital and to German Hospital; President of the American Laryngological Association, and of the Philadelphia Laryngological Society.

Thomas M. Markoe, M.D.; Professor of the Principles and Practice of the College of Physicians and Surgeons; Attending Surgeon to the New York Hospital; Consulting Surgeon to Roosevelt, Mount Sinai, and Woman's Hospital, New York City.

E. H. Bradford, M.D.; Surgeon to the Children's Hospital and to Out-patients, City Hospital, Boston.

P. S. Conner, M.D.; Professor of Anatomy and Clinical Surgery in the Medical College of Ohio; Professor of Surgery in Dartmouth Medical College, N. H.; Surgeon to Cincinnati Hospital and to Good Samaritan Hospital, Cincinnati.

Roberts Bartholow, M.D., LL.D.; Professor of Materia Medica and General Therapeutics in Jefferson Medical College, Philadelphia.

Hunter McGuire, M.D.; Professor of Surgery in the Virginia Medical College, Richmond; President of the Virginia Medical Society; President of the Association of Medical Officers of the Army and Navy, of the Confederate States; formerly Medical Director of the Army of the Valley, C. S. A., and of the 2d Corps, A. U., Va.

J. C. Reeve, M.D., Dayton, Ohio.

Charles T. Hunter, A.M., M.D.; Demonstrator of Surgery in the University of Pennsylvania; Surgeon to the Out-Wards of the Pennsylvania Hospital; Surgeon to the Episcopal Hospital, Philadelphia.

John H. Packard, A.M., M.D.; Surgeon to the Episcopal and St. Joseph's Hospitals, Philadelphia.

Thomas G. Morton, M.D.; Surgeon to the Pennsylvania Hospital, and to the Orthopædic Hospital, Philadelphia.

Theodore A. McGraw, M.D.; President and Professor of Surgery, Detroit Medical College.

Arthur Van Harlingen, M.D.; Chief of the Skin Clinic, Hospital of the University of Pennsylvania, Philadelphia.

Joseph Leidy, M.D.; Professor of Anatomy in the University of Pennsylvania, Philadelphia.

Samuel Ashhurst, M.D.; formerly Surgeon to the Episcopal Hospital, Philadelphia.

Norton Folsom, M.D.; Late Assistant Physician of the Taunton Lunatic Hospital; formerly Resident Physician of the Massachusetts General Hospital, Boston; Late Surgeon 45th Regiment U. S. Colored Troops, and Acting Medical Director of the 25th Army Corps; Author of an Essay on Hospital Construction and Organization, for the use of the Johns Hopkins Hospital, Baltimore, Md.

LIST OF ILLUSTRATIONS IN VOL. III.

FIG. PAGE

556. Application of the laryngoscope (Erichsen) 39
557. Diagram illustrating the antero-posterior reversal of the laryngeal image 41
558. Da Costa's steam spray-producer 45
559. Improved steam spray-producer with face screen attached . . 45
560. Papilloma of the larynx 67
561. Pedunculated fibrous polypus of the larynx 68
562. Extroversion of the mucous membrane of the left ventricle of the larynx 70
563. Mackenzie's laryngeal forceps 73
564. Laryngeal forceps opening antero-posteriorly 73
565. Marshall Hall's method of effecting inspiration 105
566. Marshall Hall's method of effecting expiration 106
567. Silvester's method of effecting inspiration 107
568. Silvester's method of effecting expiration 108
569. Richardson's "pocket bellows" for artificial respiration . . 111
570. Preparation of a tibia illustrating the rarefying stage of osteitis . 123
571. Preparation of a tibia illustrating the termination of osteitis in condensation or sclerosis 123
572. Ordinary anatomy of periostitis, internal view 124
573. The same, external view 124
574. Unsuccessful trephining in chronic abscess of bone . . . 134
575. Simple ulceration of bone 135
576. Strumous (or so-called "carious") ulceration of bone . . . 135
[577. Caries of the vertebræ, the column supported by ossific deposits . 136]
578. Necrosis of the shaft of a long bone, implicating the articular surface . 144
[579. Perforation by a sequestrum . . . . 147]
[580. Large sequestrum from a case of syphilitic ulceration of the cranium . 148]
[581. Extensive necrosis of the cranium . . . . . . 149]
[582. Necrosed fragment hindering the union of a fractured femur . . 150]
[583. Necrosis of broken ends of tibia . . . . . . 150]
[584. Tubular sequestrum from a stump . . . . . . 152]
[585. End view of the same bone . . . . 152]
[586. Destruction of bone by syphilitic disease . . . . . 161]
587. Syphilitic ulceration of the annular variety 162
588. Syphilitic ulceration of the tuberculated variety 162
589. Syphilitic ulceration of the reticulated variety . . . 163
590. Penetrating syphilitic ulcer 164
591. Rheumatic ulceration of bone 165

FIG.
[592. Periosteal osteoid sarcomata . . . .
[593. Periosteal osteoid sarcomata in a girl . . . . . .
594. Melanotic infiltrating cancer of bone . . . . . .
595. Malignant ulceration of bone . . . .
596. The humerus in a case of diffused cartilaginous tumor . . .
597. Cystic enchondroma . . . .
[598. Enchondroma of a metacarpal bone . . . . .
599. Model of a hand affected with numerous enchondromata . .
[600. Sub-ungual exostosis of phalanx of great toe . . . .
601. Bullous exostosis on the phalanx of a finger . . . .
602. Ivory exostosis trephined unsuccessfully on account of its great hardness . . . .
603. Diffused bony tumor of the femur and tibia . . . .
[604. Femur from a case of periosteal osteoid sarcoma . . .
605. Hypertrophy of the cranium . . . .
[606. Hypertrophy of the fibula after loss of substance in the tibia by necrosis . . . .
[607. Hypertrophy with condensation (Eburnation) . . .
608. Portions of bone removed in an excision of the elbow . . .
[609. Bone-director . . . .
[610. Butcher's saw . . . .
[611. Fergusson's lion-jaw forceps . . . .
[612. Straight sequestrum-forceps . . . .
[613. Curved sequestrum-forceps . . . .
[614. Bone-cutting forceps . . . .
[615. Another form of bone-cutting forceps . . . . .
[616. Gouge forceps for removing carious bone . . . .
[617. Strong scalpel for bone operations . . . . .
[618. Blunt periosteum-knife . . . .
[619. Another form of blunt periosteum-knife . . . .
[620. Burr for removing carious bone . . . . . .
[621. Elevator . . . .
[622. Butcher's knife-bladed cutting forceps . . . .
[623. Hey's saw . . . .
[624. Esmarch's bandage applied . . . .
625. Result of excision of the shoulder-joint . . . .
626. From the same patient, to show the amount of motion obtained .
[627. Prothetic apparatus for cases of removal of part of the humerus .
628. Result of excision of the scapula . . . . . .
629. Reproduction of the elbow-joint after excision . . . .
630. Excision of the elbow; position of extreme flexion . . .
631. Excision of the elbow; position of extreme extension . .
632. Diagram of excision of the wrist (after Lister) . . .
633. The parts removed in excision of the wrist (after Lister) . .
634. Excision of the hip-joint . . . .
635. From the same case, showing the amount of flexion obtained . .
636. From the same case, showing the amount of adduction obtained .

FIG. PAGE
637. From the same case, showing the amount of abduction obtained . 220
638. Dissection to show the uniting band in a case of excision of the hip-joint 221
639. From the same case, showing the inner openings of two old sinuses leading through the acetabulum 222
640. Another view of the same preparation, showing the end of the femur drawn into the (enlarged) acetabulum by the tendon of the psoas . 222
641. Epiphyseal lines of the femur and tibia in childhood . . . 224
642. The same femur, showing proper place for applying the saw in excision 224
643. Splint for excision of the knee 225
644. Watson's suspension-rod for excision of the knee . . . 225
645. Watson's splints for excision of the knee 226
[646. Packard's splint for after-treatment of excision of the knee (view from above) . . . . 227]
[647. The same, view from the side . . . . . 227]
[648. Ashhurst's splint for excision of the knee . . . . 227]
649. Result of a case of successful excision of the knee . . . 229
650. Excision of the knee, repair complete excepting slight carious disease . 230
651. Excision of the knee; tilting backward of the bones of the leg, or "riding of the femur" 230
652. Bones removed in a case of excision of the leg . . . 233
653. The lower surface of the astragalus in the same case . . . 234
654. Result of a case of excision of the ankle-joint 234
655. Case of removal of the os calcis, almost the whole astragalus and a portion of the scaphoid bone 236
656. The foot after recovery from excision of the astragalus . . 236
[657. Result of removal of the astragalus by an external lateral incision (Bryant) . . . . 236]
658. Result of removal of the whole of the diaphysis of the tibia . . 238
659. Shortening resulting from the removal of three inches and a half of the shaft of the femur 239
660. Posterior view of the same case 239
661. Pendulous growths from the synovial membrane . . . 241
662. Soft ankylosis 249
663. Chronic osteo-arthritis of the knee-joint (anterior view) . . 255
664. The same preparation (posterior view) 255
665. Cartilaginous growth connected with the coronoid fossa of the humerus 261
666. The acetabulum almost filled with bony deposit after recovery from hip-disease 265
667. Incipient ulceration of cartilage 272
668. Ulceration of cartilage 272
669. Section of the hip showing complete bony ankylosis of the ilium and femur 278
670. Necrosis of the acetabulum 287
671. Dislocation of the hip from disease 287
[672. Displacement of both femora; anterior view (Bryant) . . 288]

FIG.
[673. The same case; side view (Bryant) . . . . .
[674. Displacement of head of left femur, posterior view (Bryant) .
[675. Apparent elongation of the left leg in hip-disease, due to ankylosis in an abducted position. The pelvis is tilted and the leg adducted (Bryant) . . . .
[676. The same case with pelvis horizontal and leg abducted (Bryant) .
[677. Apparent shortening of the left leg in hip-disease, due to ankylosis in an adducted position. The pelvis is tilted and the leg abducted (Bryant) . . . .
[678. The same case with the pelvis horizontal and the leg adducted (Bryant) . . . .
[679. Lordosis of spine caused by hip-joint disease. Appearance in recumbent posture (Bryant) . . . .
[680. Lordosis effaced by elevating the flexed leg (Bryant) . .
681. Head and upper part of the shaft of the femur affected with chronic osteo-arthritis . . . .
682. Disease of the tarsus commencing in the joint between the os calcis and astragalus . . . .
683. Angular deformity in spine-disease . . . . . .
684. Diagram of the formation of angular deformity . . .
685. Caries of the spine with ankylosis of its posterior portion . .
686. Atlo-axial disease . . . .
687. Repair of disease of the axis . . . .
688. Deformity of the neck from disease of the cervical vertebræ . .
[689. Types of the different kinds of deformities of the hands and feet (Bryant) . . . .
690. Severe adult congenital varus . . . .
691. Congenital infantile talipes varus of medium severity . . .
692. Most severe grade of infantile congenital talipes varus . .
693. Splint for slight cases of talipes varus . . . . .
694. Dr. Little's shoe for talipes varus . . . . . .
695. Dr. Little's doubled-hinged upright shoe for severe rigid varus of the left foot . . . .
[696. Barwell's appliances for club-foot; plaster on moleskin, rubber muscles, etc. . . . .
[697. The same, tin-plate with attachment for a chain . . .
[698. Gross's club-foot shoe . . . .
[699. Sayre's club-foot shoe . . . .
[700. Shaffer's lateral splint for club-foot . . . . . .
[701. Shaffer's lateral splint applied . . . . . .
[702. Shaffer's extension shoe for club-foot . . . . .
[703. The same, view from below . . . .
[704. The same applied . . . .
[705. Modification of Shaffer's extension-shoe . . . .
[706. Correction-apparatus for various forms of club-foot . . .
[707. Club-foot shoe for night use . . . . . .
[708. Mode of stretching the foot in talipes varus by strapping (Bryant) .

FIG. PAGE
[709. Splint for talipes (Bryant) . . . . . 343]
[710. Mr. Davies-Colley's splint for talipes equino-varus (Bryant) . . 343]
[711. Kolbe's improved club-foot stretcher (inside view) . . . 344]
[712. The same (outside view) . . . . . . 344]
[713. Mr. Davies-Colley's operation for talipes equino-varus; the foot before operation (Bryant) . . . . . . 345]
[714. The same case, bones removed (Bryant) . . . . 345]
[715. The same case, foot after operation (Bryant) . . . 345]
716. Congenital talipes equinus 346
717. Front view of a congenital talipes varus of the right foot . . 347
718. Extreme congenital calcaneo-valgus 348
719. Talipes equino-varus 348
720. Talipes equino-valgus 348
721. Fully developed calcaneo-valgus 348
722. Spastic contraction of the flexors and adductors of the legs . . 349
723. Severe flat-foot or spurious valgus 352
724. Contracture of the palm and fingers from disease of the palmar fascia . 353
725. Wry-neck from contraction of the sterno-cleido-mastoid muscle . 355
[726. Shaffer's ball-and-socket apparatus for treatment of malposition of the head; the ball-and-socket joint . . . . 360]
[727. The same; chin-piece, or occipital uprights and chin-cup . . 360]
[728. Side view of the preceding figure . . . . . 360]
[729. Cap and band for extension in wry-neck (Bryant) . . . 360]
[730. Apparatus for knock-knee . . . . . . 362]
[731. Dr. Ogston's operation for knock-knee (Bryant) . . . 363]
[732. Shaffer's knee-splint . . . . 365]
[733. Bigg's apparatus for restoring position after extension of contracted knee-joint (Erichsen) . . . . . . 365]
[734. Bigg's apparatus for anterior curvature of the leg . . . 366]
[735. Apparatus for the treatment of bow-legs . . . . 366]
[736. Another appliance for the same purpose . . . . 366]
[737. Another form of the above . . . . . . 366]
[738. Treatment by weight and counter-extension of hip-joint-disease with dislocation (Bryant) . . . . . . 374]
[739. Ankylosis of hip-joint at right angles to pelvis (Bryant) . . 374]
[740. Position of leg in above case after Adams's operation (Bryant) . 374]
[741. Saw and knife for performing Adams's operation (Bryant) . . 374]
[742. Line of section of the neck of the thigh-bone in Adams's operation (Bryant) . . . . 374]
[743. Osteitis deformans (Bryant) . . . . . . 377]
[744. Enlarged bursa over the patella (housemaid's knee) (Liston) . 394]
[745. Ganglion involving all the flexor tendons of the hand and wrist (Bryant) . . . . 396]
746. Head of a humerus struck by a conoidal ball (anterior aspect) . 447
747. Posterior view of the same case 447
748. Fissured condition of shaft of humerus on the plane of resection in the same case 447

FIG.
749. Head of a humerus struck in nearly the same place by a round ball
750. Posterior view of the same case
751. Plane of resection in the same case, showing the shaft of the bone uninjured
752. Calvarium showing orifice of entrance of a round pistol-ball
753. Orifice of exit in the same case
754. Calvarium showing apertures of entrance and exit of a rifle-ball
755. Wound of exit and long fissures extending from it in the same case
756. Portion of a parietal bone showing depression after exfoliation of a small portion of the external table
757. Interior view of same segment of bone showing a healed fracture of a portion of the internal table
758. Exterior view of a portion of a frontal bone with outer table contused, but not fractured
759. Reverse view of the same specimen with portion of inner table fractured and completely detached
760. External view of a segment of a parietal bone with a depressed fracture
761. Internal view of the same specimen
762. Orifices of entrance and exit in a case of gunshot-wound of the lung
763. External condition of the wound of entrance in the same case
764. Internal view of the track of the ball in the same case
765. Partial gunshot-fracture; lateral splintering
766. Partial gunshot-fracture; perforation with fissuring
767. Resecting gunshot-fracture of the fibula
768. Upper portion of the right femur injured by a conoidal bullet
769. Injury produced by a conoidal bullet penetrating the head of the femur
770. Head, neck, and part of shaft of femur, from a case of amputation at the hip-joint
771. Upper end of tibia and lower end of femur shattered by a bullet
[772. Petit's tourniquet
[773. Application of the tourniquet (Miller)
[774. Tourniquet applied to the femoral artery
[775. Modified circular amputation in the upper third of the leg (Erichsen)
[776. Teale's amputation in the lower third of the leg (Bryant)
[777. Teale's amputation; flaps adjusted (Bryant)
[778. Flaps adjusted after amputation of the thigh by Teale's method (Gross)
[779. Conical stump (Gross)
[780. Necrosis of a stump (Gross)
[781. Large amputating knife
[782. Small amputating knife
[783. Scalpel
[784. Catlin, or double-edged knife
[785. Bone-nippers
[786. Large tenaculum
[787. Artery-forceps closing by their own spring

FIG. PAGE
[788. Artery-forceps . . . . 583]
[789. Square knot . . . . 583]
[790. Flap amputation of finger by transfixion (Erichsen) . . . 584]
[791. Amputation of an entire finger (Skey) . . . . 585]
[792. Amputation of thumb (Gross) . . . . . 586]
[793. Lines of incision for amputation of wrist and fingers (Stimson) . 586]
[794. Amputation of forearm (Erichsen) . . . . . 587]
[795. Lines of incision for amputation at elbow-joint (Stimson) . . 587]
[796. Amputation at the shoulder-joint by transfixion (Erichsen) . . 588]
[797. Amputation at the shoulder-joint; opening the capsule and making the inner flap (Erichsen) . . . . . . 589]
[798. Amputation at the shoulder-joint; holding vessels in the inner flap (Erichsen) . . . . 589]
[799. Stump after amputation at the shoulder-joint (Erichsen) . . 590]
[800. Amputation at shoulder by Larrey's method (Malgaigne) . . 590]
[801. Disarticulation at shoulder; Spence's method (Stimson) . . 591]
[802. Lines of incision for various modes of disarticulation at the shoulder-joint (Stimson) . . . . 591]
[803. Lines of incision for amputation of the toes and metatarsal bones (Stimson) . . . . 592]
[804. Lines of incision for Lisfranc's and Chopart's amputation (Stimson) . 593]
[805. Lines of incision for Chopart's, Syme's, and subastragaloid amputation (Stimson) . . . . 593]
[806. Line of incision for Hey's amputation (Erichsen) . . . 593]
[807. Line of incision for Chopart's amputation (Erichsen) . . 593]
[808. Disarticulation in Chopart's amputation (Bryant) . . . 594]
[809. Chopart's amputation; flap formed after disarticulation (Erichsen) . 594]
[810. Syme's amputation of the foot; anterior incision and disarticulation (Erichsen) . . . . 595]
[811. Syme's amputation at the ankle-joint (Erichsen) . . . 595]
[812. Syme's amputation (Skey) . . . . . . 595]
[813. Lines of incision for Pirogoff's amputation (outer side) (Stimson) . 596]
[814. Lines of incision for Pirogoff's amputation (inner side) (Stimson) . 596]
[815. Pirogoff's amputation; application of saw to os calcis (Erichsen) . 596]
[816. Bony union between calcaneum and tibia after Pirogoff's amputation (Hewson) . . . . 597]
[817. Amputation of the leg; transfixion of the posterior flap (Erichsen) . 598]
[818. Lines of incision for various amputations of the leg (Stimson) . 599]
[819. Lines of incision for amputations of the leg and at the knee (Stimson) 599]
[820. Amputation of the knee through the condyles by a modified circular method (Erichsen) . . . . . . 600]
[821. Amputation by long anterior flap at the knee (Erichsen) . . 601]
[822. Amputation at the knee by two lateral flaps (Smith) . . 601]
[823. Result of amputation of knee by two lateral flaps (Smith) . . 601]
[824. Lines of amputation at the knee and lower third of the thigh (Stimson) 602]
[825. Amputation at thigh; flaps cut from within outwards (Erichsen) . 603]
[826. Lines of incision for various amputations of the thigh (Stimson) . 604]

FIG
[827. Disarticulation of the hip by transfixion, with a long anterior and short posterior flap (Erichsen)
[828. Amputation at hip-joint; compression of femoral artery in anterior flap (Erichsen)
[829. Pancoast's aorta-compressor
[830. Lister's aorta-compressor
[831. Aneurism-needle
[832. Physick's artery-forceps (Gross)
[833. Surgeon's knot (Gross)
[834. Operation of ligation of arteries (Bryant)
[835. Ligation of the occipital artery (Gross)
[836. Ligation of the temporal artery (Gross)
[837. Ligation of the facial artery (Gross)
[838. Ligation of the lingual, external carotid, occipital, temporal, and facial arteries (Stimson)
[839. Ligation of the common carotid at the place of election (Stimson)
[840. Ligation of innominate, 2d or 3d portion subclavian, 2d or 3d portion of the subclavian (Skey), vertebral or inferior thyroid and axillary arteries (Stimson)
[841. Ligation of the brachial, radial, and ulnar arteries, and of the palmar vessels (Gross)
[842. Ligation of the radial and ulnar arteries (Pirrie)
[843. Ligation of the common iliac artery (Liston)
[844. Ligation of the gluteal, sciatic, and internal pudic arteries (Stimson)
[845. Ligation of the superficial femoral artery (Erichsen)
[846. Ligation of the posterior tibial artery at various points (Gross)
[847. Ligation of the anterior tibial artery at various points (Gross)

Revised by J. SOLIS COHEN, M.D.

DIPHTHERIA.

A FEW years ago the name of Diphtheria was unknown in England. It is highly probable that the descriptions of some of our older writers refer to this disease, which no doubt appeared then, as now, in an epidemic form; but for a very long period England had been free from its presence, and our acquaintance with its symptoms and consequences was till recently wholly derived from observations made in France, where it had been known and studied for a number of years. Prior to 1850, it must be confessed that a lingering doubt remained in the minds of many on this side the Channel, whether it did really differ from our own croup, or might not perhaps be explained merely by an unusual prevalence of croup during the existence of an epidemic of scarlatina. Careful observation seems to show that it is distinct from both these diseases, but that its relationship is in many respects so close that no better description can be given to one not conversant with the disorder than that it holds a place intermediate between them. It partakes of the febrile character and epidemic influences of the one, and of the specific exudation of the other; it combines general symptoms which belong specially to the fever, with local symptoms which belong wholly to the inflammation: and when it kills, it does so either by the general exhaustion which characterizes more or less all epidemic diseases, or by the suffocation which depends on the exudation of fibrin, exactly like that which occurs in croup.

With all this, it is a very remarkable fact that the spread of diphtheria generally coincides with the prevalence of scarlatina. Since it first made its appearance in England, the same observation has come from so many quarters that it is impossible to regard it as a mere coincidence. Indeed it has formed one of the great obstacles to our acquiring definite information regarding it, that the two diseases have so constantly run alongside of each other, and so completely merged into one another, that it has been difficult to separate them, and to distinguish between the effects produced by each. It has not unfrequently happened that in the same family, within a very short period, one member has suffered from diphtheria, and another has had an attack of scarlatina, and each has been so marked as to leave no doubt on the subject: but if the cases were not so clear, or if, as has often happened, the question of diversity were never raised at all, the two sets of symptoms would be set down to the same cause, and false inferences drawn as to the true character of the disorder.

This circumstance has no doubt given greater vagueness to the descriptions of the older writers than would otherwise have been the case, but the conclusion is unavoidable that cases occurred in their practice also, and that doubts have often arisen as to whether it was or was not a form of scarlet fever. They were not conversant, as we are, with the exudation-process, and did not discriminate between patches of lymph resting upon the surface of the mucous membrane, and a slough involving its superficial layer. They were, indeed, surprised that when the layer was detached, the membrane was found healthy beneath it; but pathology was not sufficiently advanced to draw intelligent conclusions from such observations, and we can gather little from the past that can be of use in the consideration of the special character and treatment of this disease.

History.—The first observations which, in this country at least, led to a true understanding of the nature of that false membrane which so eminently characterizes diphtheria, were made with reference to sporadic croup by Dr. Home,[1] about the middle of the last century. He first recognized the existence of a mass of fibrin, moulded to the form of the subjacent structures, and adherent to the mucous membrane, but lying quite upon its surface, "and generally lying loose upon it." Prior to this date such exudations were supposed to be part of the membrane itself, detached in the form of a slough. His descriptions, as well as those of Dr. Cheyne,[2] forty years later, prove that in the sporadic croup of their day the exudation was confined to the trachea, and did not spread to the fauces.

So truthful were these descriptions of croup, and so entirely did they correspond with the experience of British practitioners, that we were for some time disposed to doubt the correctness of our neighbors' observations; just as they imagined that there must be some error in our way of regarding croup, because it was so unlike what they were studying in the epidemic sore throat, which some years ago began to attract attention in France. Yet each set of observations was true in its own place; the two diseases were perfectly different in their origin, although they presented the curious coincidence of the exudation of false membrane, at that point where its presence interfered with one of the most important functions of life, and not unfrequently caused death by suffocation.

Bretonneau, in his Memoirs[3] read before the French Academy in 1821, was the first to give a scientific account of the epidemic disease; and its symptoms have undergone so little change, that his report continues to be a very faithful picture of the usual forms which it presents, although his theory of the local character of the disease has been now almost entirely abandoned. Till very recently this view was maintained by many of the best French pathologists; and Trousseau has perhaps been the last to yield the point, that the empoisonment of the blood, as exhibited in the general symptoms, was not merely a consequence of the local affection, and of the absorption of some material connected with the exudation. This question, though in itself one of mere abstract reasoning, which could be put to no precise test of its truthfulness, yet reached far beyond the battlefield of opposing theorists; for it offered a satisfactory reason for endeavoring promptly and effectually to remove the exudation by local applications, while it led to the overlooking of such measures as were calculated to counteract a blood-disease, which it was assumed could be prevented or cured only by the removal of the local affection. The practice thus introduced has continued more or less to form the basis of very many of the modes of treatment, and with too many the aim has only been to discover the most efficient local remedies, instead of seeking to overcome the general disorder of which we now believe the exudation to be only a part.

Symptoms.—The main symptom on which reliance is placed in the diagnosis of diphtheria, is the presence of false membrane. Like many other diseases with which we are only imperfectly acquainted, one prominent symptom, the first indeed which led to the recognition of its separate and distinctive character, has almost usurped the place in nosology which belongs to the blood-poison which gives it birth. But the more we are compelled in our ignorance to rely on one pathognomonic sign, the more surely are we exposed to the risk of error in the conclusions at which we arrive. The characters of the sign may seem to be very definite when a well-marked example is presented to us; but if it be at all obscure, we are forced to look for other indications to aid our judgment. In the investigation of diphtheria we are met on the threshold with a very prominent fact, which gives it a place at once in our nosology as a blood-poison; for so we must at present call it, while confessing our ignorance of what blood-poisoning means. It comes to us under the form of an epidemic; it attacks one individual after another; it breaks out in a given locality; singles out a certain proportion of the community for its victims; and then disappears. We ask how it came, and how it went; and the answer must be necessarily somewhat vague. Sad experience has proved that persons who have been accidentally inoculated, so to speak, with the exudation, have caught the infection and suffered from the disease. And as with other inoculable diseases, which are also certainly conveyed from the sick to the healthy through the atmosphere without actual contact, so with this there seems every reason to believe that in certain investigated instances the infection has been so propagated; and we can hardly withhold our assent to the proposition that it may be so in all, although it is not always, perhaps not often, possible to trace the source of the infection, and the means of its transmission. It matters not, however, whether the theory of the contagionists or of the non-contagionists be proved the true one; the fact still remains, that diphtheria has all the known characters of an epidemic. It is not meant to assert that no isolated case can be diphtheria, but all such must ever be received with suspicion; and if the case be really isolated, it will probably be found wanting in some of the distinctive characteristics of the disease, and may possibly be referred to some other form of throat affection.

[2] Essays on Diseases of Children, by John Cheyne, M.D.

[3] See Memoirs on Diphtheria, published by the New Sydenham Society.

But while it is admitted that the epidemic character is essential to the existence of diphtheria, it is somewhat difficult in the presence of an epidemic to discriminate cases which might have occurred as simple sore throat in its absence. The mucous membrane is perhaps only redder than usual; it may have a slight glazy exudation, or even that may be wanting. And the chief peculiarity consists in the cases being very numerous, and there being no tendency to suppuration or ulceration, as the result of the inflammatory action. Such affections of the membrane of the throat always accompany the spread of the genuine diphtheritic inflammation; and our definition must be made wide enough to embrace them, because although the chief pathognomonic sign be wanting, yet they are, without doubt, part of the epidemic, and quite as essential to a right understanding of the disease as the more marked forms to which the name is more truly applicable.

Definition.—Diphtheria may, then, be characterized as a blood-poison propagated by transmission through the atmosphere in the majority of instances, either as a miasm from the bodies of the sick, or in consequence of some atmospheric changes as yet unknown to us. This poison, after the lapse of a very few days from the date of exposure to infection, produces a general febrile action throughout the body, and a distinct local inflammation limited to the membrane covering the throat. Quite exceptionally, deep-seated abscess may form in consequence of it; but most commonly there is only simple inflammation of the glands of the neck, which are tense and tender: these accidents, however, are not essential to the disease in the same sense as the specific action on the mucous membrane.

Albuminuria.—In addition to this, an albuminous state of urine is very common in the severer forms of diphtheria. As in scarlatina, the presence of albumen is simply due to congestion of the kidney; and we conclude that in some way or other the vitiated or poisoned blood stimulates the capillary vessels so as to produce this state of congestion; but we have as yet no clue to unravel further the mystery. In the one disease the urine presents no trace of albumen during the acute stage, the congestion only appearing with the desquamation of the cuticle after the febrile condition—the scarlet fever, so to speak—has passed off; in the other it commences at a very early period of the disease, generally lasts only for a few days, and does not cling to the patient during convalescence, as is the case so often in scarlatina. It causes no surprise that we cannot explain these peculiarities, since we have no idea why the complication exists at all, when it does not accompany any other form of sore throat, nor to the same extent any other febrile disorder.

Paralysis. — Another phenomenon accompanies or rather follows upon attacks of diphtheria with sufficient frequency to establish a certain relationship between them; but as yet we can only affirm that paralytic affections may be apprehended after partial convalescence from diphtheria—after, indeed, the throat has got perfectly well, and nothing seems wanting to recovery but the due performance of the nutritive functions. This must be the gravest of the sequelæ, if it be true that patients die of paralysis of the heart[1] when no lesion whatever can be traced after death. The paralysis most frequently affects only the muscles of deglutition and of speech, but does also sometimes include nearly all the muscular tissues throughout the body; the sight becomes impaired through loss of the adjusting power of the eye,[2] the pulse fails, apparently from diminished nervous energy in the heart, the legs and arms become partially powerless, and sensations of tingling and numbness are complained of, or actual anæsthesia exists.

---

[1] Diphtheria, its Symptoms and Treatment, by Wm. Jenner, M.D., pp. 42–59.

[2] Diphtheria, by E. H. Greenhow, M.D., p. 229.

Diphtheritic fever.—The primary action of the poison when imbibed into the system is an alteration in the character of the blood. This we infer, in the first place, from the sense of malaise, the febrile action, in some instances very slight indeed, but in some very severe, which can be traced before any local manifestation occurs. This fever alone may kill, and when it does so, it is always by its assuming an asthenic or typhoid character; the patient either becomes daily weaker, and ultimately dies of exhaustion, or the case is marked by low muttering delirium, with a tendency to slough about the inflamed mucous membrane, excessive prostration, and rapid sinking; in either case the pulse is feeble and very frequent. It is to be borne in mind that this is the invariable character of the disease, however inflammatory the fever may in the first instance seem to be. In the second place, we infer the existence of blood-poisoning from the occasional appearance of purpura and sanious exudations in fatal cases, and the constant sequel of intense anæmia, even in comparatively mild cases, during convalescence.

These peculiarities are very striking, because the depression resulting from the attack is out of all proportion to its severity, and even when the fever is manifestly typhoid in its character, the subsequent weakness seems very much greater than might have been anticipated, and may end in a gradual but total failure of vital power after all danger had seemed to be at an end.

The fibrinous exudation.—The next immediate effect of the poison is the local action on the mucous membrane of the throat, which looks from the first swollen and red, as if it were the seat of active inflammation. And such no doubt it is; but it is a specific, and not an ordinary inflammation. It is quite different in its character and consequences from the ordinary inflammation of mucous membrane, and bears some analogy to that which is more commonly restricted to serous membrane; differing from it most, perhaps, in its tendency to localization. We are all perfectly familiar with the rapid spread of the inflammatory blush, from a single point, over the whole involutions of the peritoneum, with its sticky, glazy, and fibrinous exudation; we see the same exudation forming a thick shreddy coating all over the heart, or lining the entire cavity of the pleura. In diphtheria we have the same character marking the exudation, but the parts involved do not extend as far as the limits of the membrane. In many cases the patches of lymph are few and small, and the inflammation is confined to the back of the throat. In a certain number of instances the trachea, and even the bronchi, are involved;
unfrequently the membrane lining
nares is attacked more or less extensive
more rarely the exudation travels do
the œsophagus; and in a few cases
reaches up the lacrymal duct to the s
face of the eye. The laws of its ext
sion seem to be much more in harmo
with those of mucous than of serous
flammations, and there is but little dif
ence in this respect between diphthe
and ordinary sore throat, which n
either be limited to the fauces, or may
the commencement of a catarrh, end
in general bronchitis. The character
the exudation varies much in the sa
manner. When the extent of inflar
surface is small, the effusion is scar
and the deposit of fibrin of less thickn
and consistency; when the inflammat
is more extensive, it is generally
more intense, and the effusion is thic
and denser, deeper and firmer. But th
is no absolute rule in this respect.
fibrin is exactly analogous to that wh
usually covers inflamed serous membr
presenting not only the same general
pearances, but also the same microsc
cal elements.

It was at one time supposed that
discovery of a microscopic fungus
given an explanation of the whole path
gy of diphtheria. Competent obser
have, however, shown, not only that
exudation may exist without any trac
the parasite in its substance, but also
the very same form of vegetable life
be seen occasionally in some of the se
tions of the mouth when no sympt
of diphtheria, and no exudation of fil
had been present.

The ordinary consistence of the effu
is such that it is often called false m
brane; but it is sometimes scarcely
cohesive than paste, and contains
granular matter and cells than fibre i
structure. The mucous membrane
which it rests is almost always re
than usual; and when the fibrinous l
is removed, it looks raw and irritabl
if denuded of its epithelium; it is
erally also dotted over with bloody p
where the adhesion has been close
the exudation has entered the mu
follicles, and torn the tissue in it
moval.

The diphtheritic exudation is not,
ever, confined to the mucous memb
of the throat, although probably al
to be found there in a true case of
theria. It is to be seen very const
on the skin when the cuticle has bee
moved by a blister; and it is alleged
the contagion of the disease has spre
this way to persons who have had
ters applied while living in rooms w
others have been suffering from

theria. Any ulcerated or abraded surface, in persons laboring under the disease, may similarly become coated with false membrane; and not unfrequently the mucous membrane of the pudenda in female children is the seat of a similar exudation. Suppuration of an unhealthy kind sometimes attacks the mucous membrane beneath the exudation, which melts away with a gangrenous odor, leaving a slough or a foul ulcerated surface behind; and then the whole course of the disease may be changed, and the patient may fall into that low typhoid condition which is believed to be caused by the absorption of unhealthy pus.

The mere fact of exudation having taken place, apart from its value as an indication of the severity of the attack, claims our most earnest attention, from its occasional bearing on the issue of the case as a local complication. It is not the extent of surface attacked which excites apprehension, but the importance to life of the narrow chink through which air is drawn into the lungs, and the readiness with which a very small amount of thickening, or a very slight deposit on the membrane covering the chordæ vocales, may obstruct the entrance of air, and cause death by suffocation. It would appear that in different epidemics the tendency of the inflammation to spread to the larynx has varied very greatly; sometimes a majority, sometimes but a small number of the deaths resulting from this circumstance.

It is at this point that the epidemic disease comes into close relationship to the endemic inflammation of the trachea in children, known as croup. The termination of the case when death results from apnœa is identical in both diseases; the fibrinous exudation, so unusual in inflammation of mucous membrane, is also apparently identical; but, so far as we know, the cause is different. The diseases appear to be entirely distinct: the one communicable, the other having no tendency to spread; the one a simple inflammation, the other a specific fever; the general disturbance in the one case only such as is produced by the local inflammation and the difficulty of breathing, while in the other the local disorder is only one manifestation among many of a previously existing condition of blood-poisoning by which the fever is caused.

Treatment.—The fatal termination of an attack of diphtheria may follow either as a remote or immediate result of the fever itself, or in consequence of the obstruction of the larynx by local exudation; and the treatment must vary as the one or the other of these circumstances seems to be the most fraught with danger. Like the other acute specific diseases, diphtheria must be treated on general principles, inasmuch as no specific remedies have yet been discovered which have the power of destroying the blood-poisons on which they severally depend. Probably no such remedies exist. The condition of the blood during the incubation of a fever, while an infinitesimal portion only of the poison has been absorbed, must be very different from that in which the poison is again generated in unmeasured quantity, and is passing off from the patient's body to attack others who are brought within its range; and a remedy which might avail in the one condition would be useless in the other. If, as we apprehend, diphtheria is in this respect analogous to smallpox, the plan of treatment must necessarily vary with the duration of the disease, the intensity of the blood-poisoning, and the power of resistance on the part of the patient. Any specific, if such there be, can only act as a preventive, hindering the blood-changes from commencing, and cannot very well be supposed to put a stop to their progress when fully developed. The spoilt material can only be got rid of by elimination; fresh blood must be formed to take the place of that which has undergone a process of deterioration. On these broad principles must our treatment be based with reference to the fever itself; the local disease demands separate attention and different remedies.

1. In some rare cases the patient is at once prostrated by the severity of the fever; he has a brown tongue, a quick and feeble pulse, probably purpurous spots on his body, or a sanious discharge from the nose or fauces, and occasionally muttering delirium. Such cases rarely show any signs of rallying; and the freest use of stimulants affords the only chance of saving the patient or enabling him to recover from the shock of the attack.

2. If not thus prostrate from the very first, yet generally from an early period the tendency of the disease is to assume a low or asthenic type; and depressant remedies must be carefully avoided. In some cases the local inflammation is severe, and the fever is proportionately acute, and for a few days mild salines may be indicated; but even such treatment must not be persevered in too long, and the depression which follows must be met or even forestalled by the administration of stimulants. The difficulty of swallowing must not be permitted to interfere with the quantity of nourishment taken; patients who escape the first severity of the disease are still exposed to the danger of a lingering convalescence, or a gradual exhaustion of the vital powers; and hence the importance of a sustaining mode of treatment. Chlorate of potash, hydrochloric acid, and muriated tincture of

iron, are the constitutional remedies on which, according to the testimony of most writers, the greatest reliance is to be placed, combining them with diffusible stimuli or tonics, as the particular case seems to require. Each has been vaunted in turn as almost specific, and each has notably failed where it has been so misapplied. Chlorate of potash acts so completely as a charm in some cases of cancrum oris, that it is not unreasonable to suppose it may act beneficially where there is any analogous condition of the mucous membrane; in the purely non-ulcerated form of diphtheria, it is less likely to do good. Hydrochloric acid, either alone or in combination with the chlorate, is well known as a gargle and drink in scarlet fever. It seems to act partly as a local stimulus to the throat, and partly as a general blood alterative, especially in those forms of the disease in which the appearance of purpura or sanious discharge proves that important changes have taken place in the condition of the blood. Iron in all its forms is so distinctly the remedy which tends to restore the blood to its healthy condition, that its use cannot be dispensed with in a disease of which blood-changes are the commencement, and anæmia the usual termination. The tincture of the perchloride has appeared to act most beneficially in some cases of erysipelas, and its local astringent action seems to render it especially suited for the treatment of this disease. In some cases it has certainly answered even beyond expectation. [Chlorate of potash and tincture of iron are best prescribed in separate mixtures, to be given alternately, or mingled, at the time of administering, in such proportions as the medical attendant may direct. The iron must be given frequently, and in decided doses, say ten to sixty drops every two hours, hour, or half hour. The chlorate of potash should be given in doses of from two to twenty grains at similar intervals; care being taken to watch for any evidence of nephritic irritation, and to suspend it at once should such complication be threatened.]

3. Foul and unhealthy suppuration not only aggravates the general disorder, but may lead to the supervention of blood-poisoning of another kind. Pyæmia, as it is called, must be regarded as a most dangerous complication of diphtheria. Ulceration of the mucous membrane shows that the vitality of the patient is low, and calls for increased activity in the administration of stimulants and tonic remedies, while every attempt is made to convert the foul suppuration into a healthy sore, to prevent the possibility of the absorption of unhealthy pus into the system. If secondary abscesses begin to form, the liberal employment of wine and brandy, with large doses of opium, gives the only chance of recovery. The extent to which both opiates and stimulants are borne in such cases is quite surprising.

4. The local disorder claims our attention more especially when it spreads towards the larynx and trachea. The idea that the extent of the exudation was the cause of the severity of the symptoms has been entirely abandoned, and with it that meddlesome activity which deemed it necessary to apply caustics or astringents several times a day to the throat. An abraded surface, whether of cuticle or of mucous membrane, is speedily covered with the diphtheric exudation in the severer forms of the disease, even when no contact of parts is possible; and it would seem perfect madness to apply an escharotic which tends to denude the adjacent membrane of its epithelium, and prepare it for the fibrinous exudation which is certain to take its place. Such treatment, however, has been adopted, under the mistaken idea that local means could check the constitutional malady. The circumstances which seem to demand local applications are the rapid spread of the exudation, and the existence of ulceration. The application must be astringent, not escharotic; a stimulant to the diseased surface, not a destroyer of its vitality. By occasional sponging with a solution of the perchloride, or a very dilute mineral acid, or a weak solution of lunar caustic, we may hope to prevent the exudation reaching the larynx, or the ulceration assuming an unhealthy character; but the power of such means is allowed on all hands to be very limited.

[Inhalation of the fumes of lime in process of slaking is often efficient in securing detachment of morbid products from the air-passages, and their expulsion by cough. This method should always be tried, when time permits, before resorting to direct surgical procedure. Pending the resort to the lime, the vapor of steaming water may be inhaled, evolved from a special kettle, or from a pan of water heated by a portable stove of some kind by the side of the bed. In either instance the vapor can be directed towards the mouth of the patient by a funnel-shaped cowl extemporized from stiff paper.

Sprays of lime-water, lactic acid, bromide, and other drugs, are sometimes very useful for the same purpose; but the slaking lime seems by far the most reliable agent.]

When the larynx is also involved in the exudation, dyspnœa, and insufficient aëration of blood, add very materially to the sufferings of the patient, and the probability of a fatal termination; and the question naturally presents itself, whether any, and how much, benefit may be anticipated from the operation of tracheotomy. It is by no means easy to give in few words a definite answer to this inquiry, or to lay down rules which may be sufficient to guide the practitioner in deciding on his course. If we turn to statistics, we find that the fatal termination is not averted to any great extent, although in all probability some lives have been saved by the operation, which must otherwise have been lost. But it is manifestly impossible to frame a series of cases in which it has not been performed which shall be an exact counterpart to those operated upon; and without such a basis of comparison, the knowledge of the exact number of deaths and recoveries after operation is valueless. It is indeed asserted that of late years the mortality in France after tracheotomy is not nearly so great as formerly; but this may depend not so much on the results being more favorable, as on a more hopeful series of cases being selected. In such circumstances we must be guided more by general principles than by experience, and the rules for our guidance must be admitted to be based partly on conjecture. It may be assumed, then, first of all, with tolerable confidence, that when the general symptoms indicate that the attack is comparatively mild, while the danger of suffocation is imminent, tracheotomy does give a chance of life in cases otherwise all but hopeless, and that it certainly does give prompt and certain relief to the suffering immediately caused by dyspnœa, than which nothing is harder to bear. But no surgeon ought to undertake the operation, even in such circumstances, without fully explaining that relief, and relief only, from impending suffocation is its object. Secondly, when the dyspnœa is less intense, it becomes a question, whether the relief to the breathing may not help forward the process of cure which nature is working out; or it may rather be said, whether the existing amount of dyspnœa does not materially hinder the recovery, and render it more uncertain. The French surgeons are disposed to answer in the affirmative; and the opinion is shared by many among ourselves; but the practice is clearly not one that can be urged as necessary in the present state of our knowledge. Thirdly, in the very severe forms of the disease, we may well pause before recommending the operation, because it is no longer a question of the possible saving of life, but one merely of giving temporary relief. The patient is in a condition most unfavorable for the operation; and even setting aside the chances of an immediately fatal result, the fact of the operation having been performed is very apt to tell unfavorably on the issue. In addition to this, we must remember that the operation may even fail of giving relief in consequence of the trachea and bronchi being blocked up by false membrane. In such cases it can only be justified by intense dyspnœa and impending suffocation, and by the earnest longing of the patient, or the friends, to have something done to procure relief. Could we know with any degree of certainty how far the exudation extended into the trachea and bronchial tubes, we should have most valuable information to guide our decision. Auscultation should with this view always be carefully practised; but it must be confessed that the determination is a matter of extreme difficulty, and one in which the most experienced stethoscopist may fail to elicit any accurate or trustworthy information.

5. During the prevalence of the epidemic many slight cases occur, which assume more or less its specific characters, and are marked by the presence of small shreds of lymph on the fauces. An ordinary sore throat at such times does not follow its usual course, but without manifest exposure to infection is somehow assimilated to diphtheria. These generally require no special treatment, and will in all probability end in recovery without the aid of medicine. We have only to remember the tendency to depression which accompanies all the well-marked instances of the disease, and therefore in all cases we must carefully avoid any lowering remedies. No good can result from the local application of escharotics, while some risk is run of causing the exudation to spread more than it would otherwise do. Many a diphtheritic-looking throat has been produced by the unnecessary application of lunar caustic in doubtful cases.

CROUP.

General characters.—With the disease known by the name of croup, or tracheitis, as it has been sometimes called, the cynanche trachealis of Cullen, English medical men have been long familiar. Although occurring in particular localities at certain times with greater frequency than elsewhere, it presents none of the true features of an epidemic; it is much more truly endemic. It appears chiefly during the cold weather; it may visit the same locality year after year, wholly disappearing during the interval; but it does not spread to adjacent houses or villages, its victims being comparatively few, although several persons are usually attacked at or about the same time. In all these respects it has much more affinity with pneumonia than with such a disorder as diphtheria. Like the latter, however, it is marked by one very striking feature, viz., the existence, in a large number of instances, of false membrane as an exudation from a mucous surface.

With our present knowledge it is impossible to assign any reason for this peculiarity. There is no specific poison apparently introduced; the mucous membrane lining the larynx and trachea is simply inflamed; and in many cases the exudation is purulent or creamy-looking; but in the majority it is fibrinous, contrary to the usual laws governing the inflammations of mucous membrane. Why this is so, we know not; for an acute attack of bronchitis or lobular pneumonia, both not uncommon in children of the same age, is not attended by the same sort of exudation from the mucous surface of the small tubes. It is usually only when the inflammation attacks the trachea, and is localized there, that false membrane is formed; but cases are occasionally met with in which the same material may be found lining the bronchial tubes down to their minutest ramifications. It is scarcely to be hoped that we shall ever attain to a knowledge of the circumstances which determine why one exposure to cold is followed by inflammation of the parenchyma of the lungs, another by that of the lining of the small tubes, while in a third the membrane of the trachea is alone the seat of the inflammation. It is this tendency to limitation which constitutes the specific character of each inflammation, and thus distinguishes croup from laryngitis on the one side, and bronchitis on the other. The peculiar form of the exudation is not less characteristic of croup when it is observed, inasmuch as it does not accompany the other forms of pulmonary inflammation; but it is never safe to take any one symptom as pathognomonic of a disease, however close the relationship; and mistakes are constantly being made by those who rest satisfied with such methods of diagnosis.

The attack ordinarily sets in with acute febrile symptoms and a hard dry cough, which has a very peculiar sharp ringing sound, dependent on the changes which from the first occur in the larynx and trachea. The sound of the cough is so remarkable, that, when a child produces this brassy tone in coughing, the attendant is tempted to conclude, without further inquiry, that the disease is croup. There is very generally no difficulty in swallowing, any feeling of soreness of throat being confined to the windpipe, and not reaching the fauces. In some few instances, however, the inflammation is more general, and false membrane is seen on the tonsils and the back of the throat, just as ordinarily happen
theria. The breathing is alway
partly as a consequence of th
state, partly because air enters
with difficulty. As the disease
this difficulty increases, and the
recurs in paroxysms, which beco
hour more distressing. Such p
often follow a fit of coughing,
sionally come on without any
cause. In the expectoration
false membrane are often seen,
siderable relief sometimes follo
moval; but in the severer for
disease the relief is only tempo
exudation is renewed as soon as
jected, the breathing becomes
more oppressed, the skin acquire
hue, and ultimately is covered
perspiration. After several se
ineffectual struggles for breath,
seems to be stupefied by the circ
imperfectly-ventilated blood, an
tient sinks into unconsciousness.

Diagnosis.—The site of the
tion is specially the trachea; bu
fatality depends upon its invol
the larynx; and this circumst
rects our attention to the infla
action going on in that part of th
ing apparatus more than to the
of the trachea itself. Laryngiti
ease of adult life; tracheitis is
childhood: hence, if the dif
breathing is caused by some co
the larynx, we almost at onc
that in an adult we have to
laryngitis, in a child with cro
febrile symptoms are present, an
nothing visible about the thro
count for the dyspnœa. Indeed
hardly go any further in disti
these two diseases, because if fal
brane be present, its appearan
expectoration will very soon re
doubt. From bronchitis and p
it is distinguished by the coug
existence of dyspnœa, and by th
this dyspnœa being traceable
larynx. The spurious or false

diphtheria and croup the relation
close; and although it be quite
the original site of the exudativ
mation is in the former the fauce
latter the trachea, yet there are
in which at present the name giv
attack must depend simply on
sideration. whether the case
sporadically or was one of such
as could only be caused by epid
fluence. The cases which cann
termined by this rule are comp

few; and during an epidemic, genuine cases of croup may very generally be distinguished, even though the epidemic element impresses on them, to a certain extent, its own characters and features. The chief symptoms which must be relied on for this discrimination are also those on which the treatment of the two forms of disorder is in great measure based; they are those which characterize the one as a fever, and the other as an inflammation. How much there is in such a distinction those only can tell who, regardless of theories, watch the actual condition of patients under either form of disease, and can feel assured, as they certainly may be, of the benefits of depletion and starvation in the one case, of the absolute necessity for supporting and sustaining in the other. The state of the skin and the pulse help us more in this matter than any other set of symptoms; fever is associated with more burning and pungent heat of skin, with greater frequency and less power of pulse from the earliest period of the attack, and is not often associated with perspiration. But though these point the way with reference to treatment, it is by constant and repeated observation alone that we learn in each case how far the type of the disease is of a sthenic character, and are able to determine whether the patient will bear for a little while mere watching and starvation, or his tendency to prostration is such as demands our using from the first every means of support.

Treatment.—Treatment embraces especially two points: 1st, the arrest of the inflammatory action; 2d, the relief of the breathing. We cannot in this disease very often wait for such a change in the condition of the membrane as shall of itself bring relief to the breathing; the patient may die of suffocation before the inflammation subsides, however energetic our remedies may be. The state of the skin and pulse, and the hurry of the breathing, lead us most naturally to salines and antimony, as the best means of accomplishing this end. If the patient be healthy and robust, a few leeches to the top of the sternum aid in emptying the vessels and checking the exudation. The extent to which these remedies are employed must depend mainly on the constitutional strength of the patient; and in the event of diphtheria prevailing at the time, their employment must be still more sparing, because of the known tendency to depression which accompanies it, and seems to modify very much, for the time being, any coincident cases of sporadic croup. But even without any such complication, the mere fact of severe inflammatory action, with its exhausting and debilitating effects on the constitution, must put us on our guard against allowing the patient to be too much lowered by depletion, and demands a supporting plan of treatment at a comparatively early period when it occurs in the susceptible and rapidly-changing structures of childhood. The intention of this part of treatment is, if possible, to limit the febrile action before such an amount of exudation has been poured out as may run the risk of producing fatal suffocation; we do not hope or expect to arrest it altogether.

Mercury has so long enjoyed a reputation as the most powerful solvent of fibrinous exudations, that it is almost always given in croup; but one decided objection presents itself, that its action is too slow to be very available. If the patient survive long enough to be brought fully under its influence, the probability in favor of recovery is already considerable, and the result ought not to be set down to the mercury in very many cases in which it is given. Its usefulness is perhaps rather to be attributed to its action on the excretory functions.

[In the United States, the mercurial is very frequently combined with soda.]

The difficulty of breathing depends in very great measure on the condition of the larynx, and is to be explained partly by the simple fact of congestion, partly by the presence of false membrane. The depressant remedies will aid in relieving the congestion and preventing the renewal of exudation, but are powerless to remove the false membrane; occasional benefit, however, is obtained by their administration in emetic doses, which, especially with children, seem to clear out the trachea while emptying the stomach. [Inhalations of slaking lime often detach the morbid product. The vapor of water alone is sometimes sufficient for the purpose, and means for maintaining its evolution will readily suggest themselves to the professional attendant.] Our chief reliance where prompt relief to the breathing is demanded, and seems an unavoidable necessity, must be in the operation of tracheotomy. It is certainly more adapted to this disease than to diphtheria, in so far as the attack is local instead of constitutional, is an inflammation and not a blood-poisoning. The principal objection to its employment is found in the fact that the false membrane is rarely limited to the trachea, but also partly descends the bronchi; and hence that while sometimes a sufficient amount of air is admitted into the trachea, it cannot reach the lungs, because the bronchial tubes are choked up. English medical men seem now very generally to incline to the opinion that the operation, if not to be recommended, is at least justifiable, as it does

not materially increase the risk of a fatal issue, and unquestionably in some cases offers the only chance of recovery; but, to be successful, it must be performed at an early period of the attack. Such a practice is likely to meet with much opposition, from the prejudices of friends, who cannot see that there is any need for its performance; and, out of deference to their wishes, the operation is too often postponed to so late a period that it does little or no good. No operation of course can be undertaken without some risk; but the risk attending tracheotomy must be greatly increased if it is to be done in a hurry, with the immediate prospect of life being terminated by suffocation if the final plunge of the knife into the windpipe be a moment delayed. At the same
time the chance of ultimate recovery
very much diminished if the blood i
become thoroughly poisoned with un
pired carbonic-acid gas. The stethosc
may do something, but it cannot do mu
in determining the question of how
the minute tubes are obstructed. T
noise produced in the larynx and trac
generally drowns every other that mi
be heard; but if crepitation be distin
audible, indicating that inflammat
action is not limited to the trachea
the large tubes, to undertake the op
tion of tracheotomy would be quite
justifiable, except for the purpose of sa
fying the urgent desire of patients
friends, who ought to be informed t
no countervailing benefit can be loo
for to compensate the risk.

DISEASES OF THE LARYNX.

BY ARTHUR E. DURHAM, ESQ.

Revised by J. SOLIS COHEN, M.D.

IN Laryngeal Diseases the ordinary symptoms, such as pain, cough, difficulty in breathing and in swallowing, alteration of the voice, etc., often fail to indicate the precise nature and seat of the malady.

Moreover, irritation of or pressure upon the recurrent or other nerves by tumors, aneurisms, etc., as well as certain morbid conditions of the nervous system generally, may give rise to symptoms which more or less closely simulate those produced by actual disease of the larynx itself. Hence it constantly happens that some aid to diagnosis must be obtained, or the treatment adopted is as likely to be as unsuccessful in result as it is necessarily uncertain in direction. Such aid is afforded by the laryngoscope. This instrument was suggested—indeed repeatedly suggested—many years ago, but it has only recently come into general use. Its great value as an aid in the diagnosis and treatment of diseases of the larynx, though fully established, was not yet generally recognized and appreciated when the first edition of this work was published.

Historical details relative to the invention of the laryngoscope would be altogether out of place in these pages.[1] It
may, however, be stated that Dr. B.
Babington appears to have just cla
to be considered the first succes
laryngoscopist.[1] Further, it is imposs
to omit an expression of grateful ackn
edgment of the labors of Professor C
mak, formerly of Pesth.[2] To him, p

Society in 1861. Also many subsequent
tributions to foreign and British journals

ably more than to any one else, we are indebted for the earliest complete demonstration of the general practicability and value of laryngoscopical examinations, and the best methods of making them, and still more, perhaps, for the disinterested and painstaking manner in which, both on the Continent and in this country, he has published his results, and personally taught his method.

LARYNGOSCOPY.

The laryngoscope essentially consists of the laryngeal speculum, together with some contrivance by means of which a good light can be thrown upon it, when introduced into proper position in the pharynx.

The laryngeal speculum is a small plane mirror, fixed to one extremity of a slender but strong stem of sufficient length. The other extremity of the stem is fitted into a light handle, either permanently, or in such manner that it can be removed or changed at will. The mirror may be made of polished steel, speculum metal, or silver; or it may be made of silvered glass (looking-glass) mounted in a thin metal frame. The metallic mirrors are readily warmed, retain their heat well, and are so thin as to occupy but little space. On the other hand, the silvered glass mirrors are much less liable to get tarnished or scratched; no practical disadvantage arises from their comparative thickness, and there is no difficulty in keeping them of such temperature as to prevent the deposition of moisture upon them. They are, therefore, as a rule to be preferred.

In shape the mirror may be circular, ovate, elliptical, or quadrilateral with rounded angles. The three first named forms are recommended by Türck,[1] the last by Czermak.[2] For all ordinary examinations the circular and quadrilateral forms are the best, and they answer equally well. In cases, however, in which it may be necessary to carry the speculum deeply into the pharynx, or in cases in which the tonsils are much enlarged, the ovate or elliptical form is preferable.

The mirrors ordinarily supplied by the makers vary in diameter from half an inch to an inch or more. In every case the larger the mirror that can be employed, the better is the general view obtained. The stem should be straight, or only slightly curved, and four or five inches in length. It should form with the diameter of the mirror drawn to its point of junction an angle of from 120° to 125°. Moreover the mirror should be so inclined as to look somewhat downwards when the stem is held horizontally. It is advantageous to have the stem of such material that it may be bent in one direction or the other, so that different degrees of inclination may be given to the mirror according to the requirements of the case under examination.

[A flexible stem is often a nuisance in practice. It is apt to be bowed by powerful palatine muscles and thus deflect the illumination. The natural movements of the wrist supply all the motion necessary for adjusting the inclination of the mirror.]

For the illumination of the speculum when in position either direct or reflected light may be employed. But in either case, if the light should not be very powerful, concentration of the rays is desirable.

Direct sunlight answers perfectly, but is seldom available. Some other source of light *must* frequently, and *may* always be employed. Diffused daylight is rarely, if ever, sufficiently powerful. The light of a lamp concentrated by means of a glass globe filled with water—both lamp and globe being placed behind the observer, the light coming over his shoulder, was formerly recommended by Turck.[1] A somewhat similar but improved arrangement is advocated by Dr. Walker, of Peterborough.[2] But the inconveniences of any such method are obvious. Moura-Bourouillou describes, in his treatise on Laryngoscopy,[3] an instrument which he names the "Pharyngoscope." This consists of a large biconvex lens capable of bringing to a short focus the rays of light from a powerful lamp, to the stand of which it is so connected as to be easily adjusted, and moved in various directions. The whole apparatus is placed between the patient and the observer, who looks by one or other side of it. A slight modification of this arrangement is commonly used in Paris, and is recommended by Krishaber.[4] The modification consists in the addition of a concave reflector behind the light, and a shade which surrounds the lamp to such an extent as to protect the eyes of the observer from any direct rays. The condensing lens, the reflector, and the shade, are all attached to a metal ring, which is capable of being adapted and fixed by screws to almost any lamp.

Various other contrivances have been from time to time adopted for the direct illumination of the laryngeal speculum. But all are open to the objections that in their application the direction of the light is too little under the ready control of the surgeon; and too much depends upon the maintenance of the patient in proper position. He cannot be examined when recumbent. Moreover, the head of the surgeon is apt to obstruct the light if its source is behind him; and the lamp may be awkwardly in the way if placed in front of him. These and other objections are more or less completely avoided by employing reflected light for the illumination of the speculum. Czermak first suggested the use of a modification of Ruete's large ophthalmoscopic reflector for this purpose. And some such method as that which he originally suggested still appears the most convenient and most generally applicable. At any rate it is the method commonly adopted in this country and in Germany.

[Attempts have been made in Europe and America to utilize electricity as an illuminating agent, both by incandescence of platinum wire, and by incandescence of vacuum; but these efforts, though promising, are as yet by no means successes.]

The source of light is placed on one side of and somewhat behind the head of the patient, who should, if practicable, be seated near the corner of a table. The rays are then reflected from and concentrated by a circular concave mirror duly arranged immediately in front of the face of the surgeon. The mirror should be three or four inches in diameter, and should have a focal distance of about twelve inches. It may be perforated or not in the centre. If perforated it may be placed in front of one eye, and the view may be taken through the perforation. If not perforated it may be arranged in front of the forehead and nose, and between the eyes; or lower down in front of the nose and mouth. In either of these arrangements both eyes may be used; in the former looking below, in the latter above the reflector. The perforated reflector should theoretically give the more perfect view. But practically the imperforate reflector is found to be as efficient in all ordinary cases; and it possesses the great advantage of permitting the equal use of both eyes. The reflector may be held in the hand, when the hand is not required for any other purpose; or it may be supported on a stand in such a manner as to be freely movable in all directions. In Tobold's arrangement it is connected with the stem of the lamp, or the light-concentrator. Generally, however, it is attached to the head of the surgeon by means of a strong spectacle frame, an elastic frontal band, or a steel spring passing over the vertex. The first method is best adapted for the perforated reflector; the second for the imperforate reflector in front of the forehead; and the third if the reflector is worn lower down. Czermak's original plan of fixing the stem of the reflector at right angles to a piece of wood to be held between the teeth may be considered obsolete. In any case the reflector should be connected with its support either by a ball and socket joint, or in such other way as permits it to be turned easily in any required direction.

As a source of light, any lamp which burns with a bright, steady, full bodied flame, may be employed. A good moderator or reading-lamp, or an Argand gas-burner, answers perfectly well for all ordinary purposes. But it is desirable to have the lamp so arranged that it can be raised or lowered in position, and moved from side to side. Mackenzie's "rack movement laryngoscopic lamp,"[1] which readily admits of perpendicular and horizontal movement, is admirably adapted for use in the consulting room.

The light of the lamp may be advantageously concentrated by means of one or more lenses placed in front of the flame, and a concave reflector or white reflecting surface placed behind it. Of all the so-called "light concentrators" which I have seen, I believe Mackenzie's is the best for ordinary use. It consists of a metallic cylinder having a short branch which bears a plano-convex lens two or three inches in diameter. The cylinder replaces the glass chimney of the Argand gas-burner; and its branch is so situated, and of such dimensions, that the lens is opposite the middle of the flame, and receives and concentrates a large body of luminous rays. Dr. George Johnson's light-concentrator has the advantages of portability and readiness of application to any ordinary lamp. It consists of a plano-convex lens, and a concave reflector attached to a metal ring, which by means of a spring clip or screw can be easily fixed to the brass collar of the lamp glass. Tobold's apparatus contains two lenses. It is very efficient in working; but it is heavy and cumbersome, and can only be applied to a lamp especially adapted for it.

For purposes of demonstration, and sometimes in operating, it is advantageous to have command of a more brilliant light than any ordinary lamp can afford. Such a light may be obtained by means of the electric, magnesium, or oxyhydrogen lantern. Of these, the last named, or some modification of it, is most easily available and most manageable. The apparatus employed at the Hospital for Diseases of the Throat answers admirably. The so-called "Medical Lantern" of Dr. Thudichum,[1] which he especially recommends for use in rhinoscopy, is equally adapted for laryngoscopical and other examinations. In this apparatus the hydrogen flame is conveniently replaced by that of a spirit-lamp.

---

[1] Made by Mayer and Meltzer.

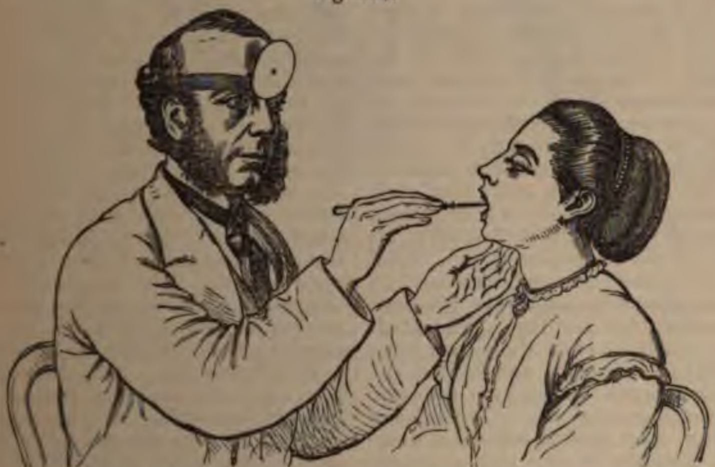
In cases in which the diagnosis is doubtful, or in the treatment of which difficult operative measures are needful, it is sometimes well to wait until sunlight is available. In making an examination by sunlight, a plane rather than a concave reflector should be used. The latter throws too brilliant a light; and moreover the rays concentrated by it may possibly burn the patient if proper care is not taken.

In all cases in which sunlight, or any other powerful light is employed, the eyes of the surgeon should be protected by a plain shade, or by the hollow conical eye protectors,[1] which are figured in use in the chapter on Rhinoscopy (p. 228, fig. 297). If a comparatively feeble light is employed, it is advantageous to darken the room in which the examination is made.

The general arrangements for making an ordinary laryngoscopical examination by means of the reflector and artificial light are represented in fig. 556.

The lamp, the mouth of the patient, and the eyes of the observer should be as nearly as possible in the same plane. If the laryngeal speculum is held in the right hand of the surgeon, the lamp should be placed on the right side of the patient, and *vice versa*. If, as may sometimes be convenient, the lamp is placed above and behind the head of the patient, the vertical plane must be preserved; but the speculum may be held with equal advantage in either hand without risk of obstructing the light.

Fig. 556.



Application of the laryngoscope. The tongue should be drawn forwards (Erichsen).

The patient should if possible be comfortably seated opposite the surgeon in a nearly erect position. His body should lean somewhat forwards, and his head should be inclined slightly backwards; but should not be thrown so far back as is often done. Sometimes it is advantageous to employ a "head rest," which may either be fixed to the back of the chair, or may have a separate stand. When in proper position, the patient is directed to open his mouth as widely as possible, and to breathe quietly but deeply. His tongue may be protruded, and held by himself or by the surgeon, the fingers and thumb being covered by a soft towel or handkerchief to prevent slipping; or it may be kept within the mouth, and gently pressed forwards against the lower teeth, an attempt being made at the same time to depress and flatten or render concave its posterior part. Sometimes one plan, sometimes the other is found to be the more effectual. Meanwhile the surgeon arranges his reflector so as to throw the light into the open mouth of the patient. When he has succeeded in illuminating the middle of the soft palate, the uvula, and posterior pharyngeal wall by a bright disc of light, he may proceed to introduce the laryngeal speculum.

---

[1] Made by Orchard, of Kensington. See Thudichum On Polypus of the Nose and Ozæna, p. 5. Churchill, 1869.

[1] Made for me by Messrs. Weiss.

The handle of the speculum should be held somewhat "pen-like" between the thumb and the fore and middle fingers of one hand or the other. The speculum should be slightly warmed previous to its introduction, either [by holding the reflecting surface] over the lamp [until the condensed moisture is dissipated from it] or by momentary immersion in hot water, in order to prevent deposition of moisture upon its surface.[1] Care must be taken, however, that it is not made too hot. Its temperature may be easily tested by the hand or cheek of the surgeon. [For personal safety, the hand is far preferable to the cheek.] The speculum should be introduced with its reflecting surface directed downwards and forwards. It should be carried backwards through the cavity of the mouth, deliberately, confidently, and steadily, and then applied with gentle but firm pressure against the uvula and neighboring portions of the soft palate. Uncertain, hesitating, and hasty movements of the instrument are liable to give rise to objectionable titillation. In its passage through the mouth it should not come in contact with the tongue, nor indeed with any other parts than those against which it is to be placed. As a rule it should not be carried so far back as to touch the posterior pharyngeal wall. Sometimes, however, especially in certain exceptional cases, this may be done with considerable advantage. [The editor almosts invariably rests the mirror upon the wall of the pharynx, and finds it the most advantageous method, as the rule, rather than the exception.] The hand of the surgeon must be kept somewhat down and well towards its own side, so as not to obstruct the light. The third and fourth fingers may rest against the chin or cheek of the patient. [When the mirror rests upon the pharynx there is no occasion to support the fingers upon the face of the patient.] The stem of the instrument should lie in or near to the corresponding angle of the mouth [or directly in the middle line, as may be most convenient]. In a large proportion of cases no difficulty is encountered, and the patient suffers comparatively little inconvenience.

When the speculum is thus placed in position and well illuminated, it exhibi
to the surgeon images of those parts
the larynx upon which the rays reflecte
from its surface are made to fall. It mu
be borne in mind, however, that as
necessary consequence of the position
the mirror in relation to the eye of t
observer on the one hand, and to t
larynx of the patient on the other, t
parts appear in the image as though
versed antero-posteriorly. And they a
thus conventionally represented in
ordinary laryngoscopic diagrams.

This so called "reversal" or "inversio
of the image is illustrated by fig. 557 (

---

[1] Various expedients have been suggested with a similar view. Thus, Dr. H. G. Wright contrived a speculum, the temperature of which was maintained by a wire placed behind the mirror and heated by galvanic action. Dr. Buzzard recommends that the surface of the mirror should be covered with a film of glycerine. But no plan answers better than the simple one above-mentioned; nor is any other so easy of application.

rule the best subjects for laryngoscopic examination—not the worst, as might be supposed. Their desire for benefit affords a stronger stimulus to patience and self-control than can actuate the healthy; and, moreover, they are usually accustomed to expose their fauces for inspection, and to submit to local applications, by which indeed the normal sensitiveness of the parts may have been diminished.

The most common sources of difficulty are as follows: general nervousness and excitability of the patient; fancied or real inability on his part to open his mouth sufficiently wide, and awkwardness in the management of his tongue; relative largeness, or some swollen condition of the tongue; malformation or deformity of the soft palate and neighboring parts from ulcerative disease, and subsequent contraction of cicatrices; elongation and thickening of the uvula; enlargement of the tonsils; pendency of the epiglottis; and, lastly, extreme sensitiveness of the uvula and soft palate, either natural or resulting from existing inflammation or ulceration.

Difficulties arising from the first three sources may be overcome almost invariably by patience and judicious management on the part of the surgeon, and a little practice on the part of the patient. Hastiness in manner, and in method of proceeding, should be avoided; and every effort should be made to encourage, reassure, and inspire confidence. By his own example the surgeon should show the patient how to open his mouth, and should demonstrate the slightness of the inconvenience caused by the introduction of the speculum. If proper directions are given, and the patient is induced to practise occasionally by himself before the looking-glass, he will probably return in the course of a few days comparatively well able to display his fauces, and to submit to the needful examination.

By one or other of the methods already indicated (p. 39) the tongue may generally be kept out of the way. If, however, these methods fail, and the tongue still rises so high as to obstruct the view of the soft palate, etc., the patient should be directed to make a few deep inspirations, and alternate them with the repeated pronunciation of the broad vowel "*a*" (ah). He should breathe through the mouth only; not through the nose. In this way the tongue may often be brought into favorable position. Sometimes a broad spatula or tongue depressor may be advantageously used. But as a general rule the introduction of any unnecessary instrument into the mouth should be avoided.

Occasionally by sliding the finger along the tongue (the speculum being at the same time introduced and illuminated), an effort at vomiting is produced, during which the tongue being depressed and the larynx raised, a good though a momentary view may be obtained.

In cases in which *the soft palate is unusually short, and the uvula small and thin*, the speculum is apt to slip up somewhat behind them, and to become partially hidden. Under such circumstances it is better to hold the instrument as nearly as possible in its proper position without touching or resting against the soft palate.

An elongated and thickened uvula may obscure the view by hanging below, and turning round the inferior border of the speculum. The employment of a larger speculum, or a little manœuvring of the instrument, serves to obviate this source of difficulty for the time being; and it may be permanently removed by appropriate measures.

Considerable embarrassment is often caused by *chronic enlargement of the tonsils*. In such cases a narrow, elongated, elliptical speculum should be used, and carried somewhat more deeply into the pharynx than is usually necessary. Enlarged tonsils are often so little sensitive that the speculum may be pushed well in between them without causing much discomfort.

Pendency or projection backwards of the epiglottis is a frequent source of considerable difficulty. Gibb states as the result of his observations that some such abnormal condition is to be found in eleven per cent. of otherwise healthy individuals.[1] It depends upon undue elongation of the glosso-epiglottidean ligaments or folds of mucous membrane, together with relaxation or weakness of the muscular fibres they contain. The degree of obliquity observed varies greatly in different cases, and to some extent in the same case under different conditions. In some instances the epiglottis hangs almost horizontally over the entrance to the larynx; but more frequently its deviation from the normal erect position is comparatively slight, or even only occasional. Laryngoscopic inspection is of necessity proportionately impeded. The greatest difficulty is often experienced in obtaining a satisfactory view, and sometimes even partial success appears to be impossible.

In all cases of pendent epiglottis it is necessary to carry the speculum further backwards and downwards, and to make
its reflecting surface look more fo
than is desirable in the normal co
of parts. Sometimes its lower
must be placed against the posteri
of the pharynx. When the specu

Difficulties arising from unusual sensitiveness of the uvula and soft palate may generally be overcome by patience and dexterity on the part of the surgeon, and a little practice on the part of the patient. During the earlier attempts the speculum should not be maintained too long in contact with the parts. It should be at once withdrawn if decided retching is produced; and short of such effect, if the irritability is great, it is better to apply the speculum repeatedly for a moment or two, and remove it as often, without caring to obtain any view until the parts have become as it were accustomed to the presence of the instrument. When once efforts at vomiting have been excited, there is little probability of success until a future occasion. Preparatory measures of various kinds have been from time to time suggested; some of these are probably useful; others have been proved by experience to be altogether useless. Many owe their accredited efficacy to the confidence with which their exhibition has inspired the patient. The internal administration of bromide of ammonium or bromide of potassium in full doses has been strongly recommended and extensively tried, but with variable results. Gargles containing bromide of ammonium are said by Gibb to produce "moderate anæsthesia" of the fauces in twenty-four hours.[1] Türck reports favorably of the repeated application to the fauces of a mixture (recommended by Bernatzik) which consists of three grains of hydrochlorate of morphia, one drachm of alcohol, and half an ounce of chloroform.[2] But all such applications as this would appear more likely to inflame than to soothe the sensitive parts. Alum gargles, or solutions of alum or some other astringent in the form of spray, are often useful. Occasionally a few whiffs of chloroform may be advantageously inhaled. But by far the best and easiest plan, so far as I know, is to direct the patient to suck a little ice immediately before submitting his throat for examination. The result is generally satisfactory.

[Dr. Rossbach has recently recommended local refrigeration for two or three minutes, by ether-spray or the like, of the superior laryngeal nerve, where it lies subcutaneously over the thyro-hyoid membrane, just at its point of penetration of that structure. Some experiments, instituted at the writer's public clinic, have sustained the observations of Dr. Rossbach in a number of instances, although the plan has sometimes failed utterly.]

Besides the various sources of difficulty thus discussed, there are others which depend upon inexperience and want of dexterity on the part of the surgeon. These can only be obviated by careful practice. The surgeon should not only familiarize himself with the management of the laryngoscope, but also with the relations and appearances presented by the healthy living parts when viewed by its aid. In color especially, the mucous membrane of the larynx seen during life in the laryngeal mirror looks very different to what it does when examined after death on the *post-mortem* table. It is very possible for the tyro in laryngoscopy to mistake the natural tint of some parts for a certain degree of inflammatory redness.

The general appearances and relations of parts as seen in the laryngeal speculum need no special description. They may be learnt by the careful study of a larynx removed from the body, or by *auto-laryngoscopy*, or by the examination of the larynx of some living subject. But with regard to the color presented by the different parts in a state of health, the following observations may be made.

The lingual surface of the epiglottis appears of a yellowish or pinkish drab color. Its upper border is decidedly yellow. Its laryngeal surface, especially the "cushion," varies from a pinkish yellow to a deep pink; sometimes it appears bright red—so bright, indeed, as to suggest the idea of the existence of an inflammatory condition. The aryteno-epiglottidean folds are pale pink. Stoërk accurately describes them as being about the same color as the gums. The mucous membrane covering the arytenoid cartilages is still pink, but of a somewhat deeper tint. The false vocal cords are perhaps slightly deeper pink still. The true vocal cords are distinguished by their glistening pearly whiteness; but sometimes they are slightly grayish. The cricoid cartilage is recognized by its well marked yellowness. The tracheal cartilages appear of a yellowish drab color; and between them the mucous membrane is pale pink.

A great variety of different instruments have been devised from time to time for the several purposes of demonstrating to others the appearances of the larynx under examination; of holding the laryngeal mirror in a position so as to leave both hands of the surgeon free; and of depressing the tongue at the same time the laryngeal mirror is introduced. Some of these are useful; others are rendered unnecessary by the aid of a skilful assistant. For descriptions of all such contrivances reference may be made to the special treatises already quoted.

[1] The Laryngoscope in Throat Diseases. Op. cit. p. 46.

[2] Allgem. Wiener Med. Zeit., p. 98. 1833.

General Remarks on the Treatment of Diseases of the Larynx.

The laryngoscope affords most valuable aid, not only in the diagnosis, but also in the treatment of the various diseases of the larynx. Guided by the view obtained, the surgeon is enabled to make such local applications as may seem desirable, with accuracy and precision, and to perform many different operations—such as scarifying the mucous membrane, opening abscesses, removing growths, etc., with certainty and safety. The use of the laryngoscope has altogether set at rest the doubts formerly entertained as to the practicability of introducing brushes, probangs, and other instruments into the larynx.[1] Such doubts have in past time unquestionably prevented the adoption of methods of treatment, that in many cases, might have been eminently successful. But nowadays it would appear that the danger is in the opposite direction, and that the tendency is rather to carry out local treatment too vigorously, or to rely upon it too exclusively.

Remedial applications may be made to particular parts, or to the whole of the interior of the larynx with variable advantage by several different methods. It appears desirable to give at once a general description of such methods, and to refer in the succeeding sections to the special modifications requisite in the treatment of each particular malady.

Solid substances may be applied either in the mass or in powder. If applied in the mass, some form of caustic holder is requisite. No instrument answers so well, and at the same time is so safe, as a piece of moderately thick aluminium or silver wire mounted in a slender handle, and hollowed into a tiny cup, or roughened at the extremity. The roughened extremity may be dipped into various substances, as nitrate of silver, chloride of zinc, etc., while in a state of fusion; and a sufficient quantity may be taken up in a bead-like form, or as a thin coating. The wire may be easily bent at any angle requisite, and there is no danger of any considerable portion of the substance breaking off and falling upon parts it was not intended to reach. Such danger might arise during the use of some of the various complicated caustic holders that have been devised for similar purposes. By aid of the laryngoscope a small caustic bead, prepared in the manner described, may be definitely applied to any particular point; or if the wire is coated to a sufficient extent, the general surface may be wiped over.

Powders can only be applied to the mucous membrane generally. They may be inhaled through a tube, as recommended by Fournié, or, far better, blown in by means of Rauchfuss's insufflator[1], or some modification of it. The insufflator, duly charged, is introduced into the back of the fauces, with the extremity turned down towards the larynx. The patient is then directed to make a slow steady inspiration, and while he is doing so the India-rubber ball of the insufflator is suddenly compressed. Under such circumstances it is obvious that a considerable portion of the powder must be diffused over the mucous membrane of the larynx. The powders that have been used with most advantage in this manner are tannic acid, alum, acetate of lead, sulphate of zinc, sulphate of iron, calomel, and in some exceptional instances, nitrate of silver. It is scarcely needful to add that in every case the substance used should be very finely pulverized. Sometimes it may be advantageously diluted with two or three or more parts of sugar of milk.[2]

Liquids, or substances in solution, may either be applied by means of a full-bellied camel's-hair brush, or small sponge, mounted on a properly curved aluminium or silver wire or whalebone stem; or they may be injected in a fine shower from Gibb's "laryngeal syringe" or "hand atomizer;"[3] or they may be inhaled in the form of "spray," produced by one or other of the various instruments devised for the purpose. Strong solutions, especially those of a more or less caustic nature, should, as a rule, be applied by the brush. Among the more generally usefu of such solutions may be enumerated those of nitrate of silver (℈ij or ʒij to ℥j of distilled water), perchloride of iron (ʒij o more of the tincture to ℥j), pure carbolic acid (ʒss or more to ℥j), alum (a saturated or weaker solution), sulphate of copper (saturated or weaker solution), etc. Glycerine or honey may be advantageously mixed with these solutions in considerable proportion, in order to give them viscidity, and render them more adhesive Iodine (gr. xx), iodide of potassium (gr v), and olive oil (℥j), forms an applicatio recommended by Dr. Marcet.[4] The "gly cerinum acidi tannici" (B. P.) may also be used in some cases. By means of the brush all such substances may be applied with a certain degree of precision to any particular part. In some instances even nitric acid, chromic acid, and other powerful escharotics have been thus applied to ulcers, warty growths, etc., with safety and advantage. At the moment the brush is to be introduced into the larynx, the patient should be directed to make a full deep inspiration in order to dilate the aperture as widely as possible. In cases in which the epiglottis is pendent, it is often very difficult to get the brush beyond it into the larynx. Under such circumstances the laryngeal syringe may be more successfully used, inasmuch as its extremity may be guided round, and made to raise the pendent valve to a sufficient extent.

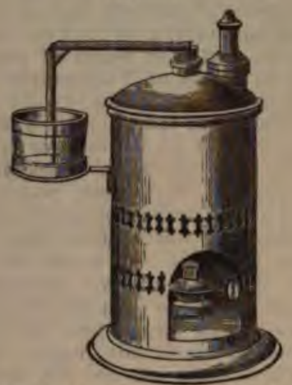
[4] On Diseases of the Larynx, by W. Ma cet, M.D., p. 18. 1869.

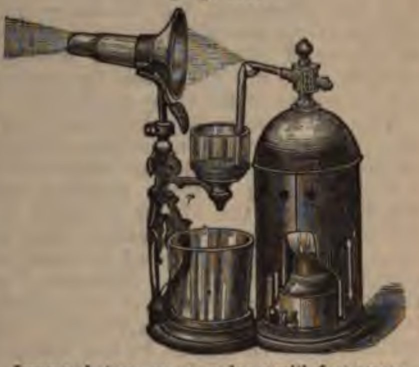
The inhalation of "atomized fluids," or spray, in the treatment of diseases of the air-passages, though suggested long previously, was first shown to be generally practicable by Sales-Giron in the year 1858.[1] Since then the great value of this method has been fully established, and various improvements have been from time to time effected in the apparatus employed.[2] The "spray-producers" at present in ordinary use, consist of two tubes (Bergson's tubes) fixed at right angles to one another; of these, one, placed horizontally, is connected at its distal extremity with some apparatus by means of which a strong current of air or steam can be continuously projected through it; and the other, placed vertically, dips into a bottle or other small vessel containing the medicated fluid. The proximal extremity of each tube is terminated by a very fine orifice; and the orifice of the former tube is immediately over that of the latter. When a current of air or steam is made to rush forcibly from the orifice of the one tube over that of the other, it causes the medicated fluid to rise, and breaks it up as it issues, and diffuses it in an exquisitely fine spray. In Dr. Andrew Clark's well-known instrument (as well as in the various modifications of it adopted by different makers), air is employed, and the current is kept up by means of an India-rubber "handball" bellows. All such instruments, however, though unquestionably useful, are far inferior, for several obvious reasons, to those in which a jet of steam is employed, as first suggested by Dr. Siegle, of Stuttgart. The steam is derived from water contained in a small boiler heated by a spirit-lamp. Figs. 558 and 559 represent two very efficient modifications of Dr. Siegle's original pattern.[1]

Fig. 558.



Da Costa's steam spray-producer.

[Fig. 559.



Improved steam spray-producer with face screen attached.

The use of this instrument involves no continuous exertion like the handball spray-producers: and what is of far more importance, the atomized fluid is mixed with and propelled by a current of warm steam instead of cold air. A great variety of different solutions, the strength being varied according to circumstances, may be advantageously inhaled in the form of spray. Among them may be especially mentioned the following—the medicament being in each case in about the proportions specified to an ounce of water:—Alum (gr. x to gr. xx), tannic acid (gr. j to gr. xx), perchloride of iron (gr. ⅛ to gr. ij, or of the tincture ♏ x to ♏ xxv), as "astringents;" common salt or chloride of ammonium (gr. x to gr. xxx), chlorate of potash, borax, or iodide of potassium (gr. iij to gr. x), as "alteratives;" and watery extract of opium (gr. ¼ to gr. ½), hydrochlorate of morphia (gr. ⅛ to gr. ⅓), or fluid extract of hemlock or hyoscyamus (♏ iij to ♏ x), as "sedatives" or "anodynes." Very weak watery solutions of iodine, and chlorine (or chlorinated soda), tar water, lime water, weak alkaline solutions, sea water, the saline waters of many mineral springs,[1] and other solutions too numerous to mention have also been largely used in different cases with variable advantage. Sulphurous acid in spray has recently been very strongly recommended in the treatment of various affections of the throat and larynx by Dr. Dewar and others. But experience seems to show that great caution is requisite in the use of this material. Though doubtless beneficial in some cases, in many it has proved not only less efficacious, but far more mischievous than was anticipated. Solutions of nitrate of silver and other powerful metallic salts are unsuitable for application by means of the spray-producer.

---

[1] See the elaborate report by Poggiale read before the Académie de Médecine, Paris, January 7, 1863, and the discussion thereon. Also Dr. Beigel's treatise on Inhalation, London, 1866, in which are full details as to the history of this method of treatment, and descriptions of the different forms of apparatus devised.

[2] Mackenzie especially recommends Mayer's modification of Matthieu's apparatus, which is worked by means of a pressure-pump; and acts on a different principle to that described above. The fluid is forced through a fine orifice and projected against the interior of a vulcanite drum. It thus becomes broken up into a fine spray. Op. cit., p. 90.

[1] These as well as other forms of this apparatus are made by almost all instrument makers.

Many substances may be inhaled with very great advantage in the form of vapor or gas. In various acute or subacute affections nothing is more soothing and beneficial than the almost constant inhalation of warm steam, either plain or charged with some narcotic or anodyne element. The "hemlock inhalation" of the British Pharmacopœia is very useful; it is rendered less disagreeable and perhaps more efficacious by the addition of a pinch or two of fresh dried hops; or the hops may be infused alone in the hot water; or a portion of opium may be added; in some cases vinegar is useful and pleasant. In chronic cases, according to their nature, the vapor o
pentine, or some aromatic terebintl
or iodine, or calomel may be inhale
very great benefit. For the inhala
steam, plain or medicated, vario

[1] In 1849 Auphan, of Euzet-les-Bains, originated the idea of atomizing the mineral water by throwing a jet of the liquid against the wall of the inhalatory. After a short time the same system was adopted in Lamote-les-Bains. But Sales-Giron first constructed at Pierrefonds an apparatus through which the fluid was subdivided into a fine mist, which was inhaled by the patients with great benefit.—Beigel, op. cit., p. 6. At many of the Continental Spas arrangements are now made for the inhalation of the atomized waters.

strument are in position, the circuit is completed by pressing upon a small trigger on the handle of the laryngeal portion of the galvanizer. The galvanizer may be applied several times at the same sitting, it being kept in for a few seconds each time.[1] Other instruments have been devised with similar intent, but the one described appears to have found most favor with practical laryngoscopists. It is recommended by George Johnson, Smyly, Fauvet, Tobold, Marcet, Gibb, and others.

CATARRHAL LARYNGITIS.

Acute Catarrhal Laryngitis is a formidable, and not very rare affection. It varies greatly in intensity, and consequently in the degree of danger to which it gives rise. It may occur at almost any period of life, but is most frequently met with in adults of plethoric habit.

Exposure to cold and damp, especially after prolonged exertion of the voice, and when the general powers are reduced by fatigue, is the most common cause.

As a rule the fauces are first affected, and the inflammation spreads with variable rapidity to the larynx. Sometimes, however, the malady commences in the larynx itself, and is confined to it.

The earliest *symptoms* are those of an ordinary "sore throat." The patient complains of dryness, soreness, and a sense of constriction about the upper part of the throat, together with tenderness on pressure over the larynx, and pain and difficulty in swallowing. The feeling of discomfort is constantly referred to the pomum Adami, or its immediate neighborhood. Respiration soon becomes impeded; the patient experiences a sense of oppression, and from time to time feels it needful to make an effort to breathe deeply. His voice becomes thick and husky; and occasionally he tries as it were to "clear his throat" by a dry, harsh, or half suppressed and painful cough. Accompanying these symptoms there is more or less general febrile disturbance.

As the malady advances, the symptoms increase in severity; and the patient becomes restless and anxious. The face is flushed, the skin hot and dry, the pulse hard and quick. Respiration becomes more and more seriously impeded. Inspiration is difficult, protracted, and painful, and is accompanied by a wheezing, whistling, or harsh throttling sound. The chest is not fully expanded; and there is diminution of the respiratory murmur. Expiration remains comparatively easy; for the warm, moist air from the lungs irritates the inflamed and sensitive mucous membrane much less than the colder, drier air, inspired from without. The dyspnœa is constant in so far as it depends upon constriction of the glottis from swelling of the mucous membrane; but it becomes greatly aggravated at intervals in consequence of spasmodic action of the muscles. The voice, at first husky and hoarse, soon becomes low in tone, or "cracked" and uncertain, and finally is altogether lost, the patient speaking only in a whisper. In some cases there is but little cough. In others the cough is frequent, and harsh, husky, or stridulous in character. Cough may be provoked either during inspiration by the contact of cold dry air, or during expiration by the presence of little masses of secretion. The sputa in the earliest stages are very scanty, and consist of little more than saliva; later they become somewhat more abundant, but are still semitranslucent, though more or less tenacious and viscid, containing laryngeal mucus as well as saliva; still later they are opaque and grayish, and sometimes are slightly streaked with blood. After any of these have been coughed up a painful sense of rawness about the part is often experienced. The small, firm, agglutinated masses which are occasionally coughed up, probably come, according to Krishaber, from the ventricles of Morgagni. The difficulty of swallowing, almost invariably noticed as one of the earliest symptoms, becomes more and more pronounced as the malady progresses. "*Difficulty of deglutition* for which no adequate cause is visible in the fauces," speedily followed by "*difficulty of breathing* for which no adequate cause can be discovered in the thorax," are, in the words of Sir Thomas Watson, "among the earliest of the symptoms that bespeak danger, and ought to excite alarm."[1]

If the malady advances to the next stage, and no relief is afforded, the general distress of the patient becomes intense. He labors and struggles for breath. His anxiety and restlessness are extreme. He cannot lie down; or if, exhausted, he tries to do so, he soon starts up involuntarily, gasping for very life. His countenance becomes pale and livid, or even ghastly; his eyes protrude; sweat pours from his forehead; his skin is cold and clammy; his pulse becomes weak and intermittent; exhaustion, drowsiness, and perhaps delirium supervene; and lastly, he dies suffocated—either almost suddenly from spasm of the larynx, or by a process of comparatively slow asphyxiation.

The morbid changes which give rise to the symptoms thus described may be

---

[1] Lectures on the Principles and Practice of Medicine. 4th edit., vol. i., p. 831.

traced during life by aid of the laryngoscope, or made out after death on post-mortem examination.

On *laryngoscopical inspection* the mucous membrane of the larynx is seen to be of an unnatural scarlet red color, and more or less thickened or swollen. Occasionally superficial erosions may be recognized here and there; but neither deep nor extensive ulceration is observed, or only extremely rarely. The redness and swelling, as a rule, are especially manifest in those parts in which the mucous membrane is thick, and is supported by abundant loose submucous areolar tissue. Thus the aryteno-epiglottidean folds, the mucous membrane of the vestibule, the false vocal cords, and the laryngeal aspect of the epiglottis present these appearances in the most marked degree; and generally speaking, they are affected in extent in the order in which they are named. The mucous membrane of the true vocal cords, on the other hand, being comparatively thin, and closely connected with dense subjacent tissues, is less swollen, and less uniformly reddened. Sometimes it is marked by red striæ or patches. Sometimes it seems only to have lost its pearly whiteness, and to have become dull, clouded, or pinkish in color, and somewhat unduly protuberant. But, as may readily be understood, in many cases the true vocal cords are almost or entirely concealed from view by the swollen parts above. Still more is this the case with the parts of the larynx below the glottis, and the trachea, which, nevertheless, not infrequently suffer from extension of the inflammation. The epiglottis is usually seen to be erect, rigid, and swollen. It is consequently unfitted to fulfil its natural valvular office. Sometimes it may be felt by the finger as a smooth, rounded, "cherry-like" intumescence. Occasionally it gives rise to sensations similar to those produced by the presence of a foreign body. The patient "feels as though he had something in his throat."

The condition of the epiglottis serves in great measure to explain the difficulty in swallowing, and the sense of suffocation often experienced when the attempt is made. The dysphagia is still further accounted for by the pain caused by the necessary movement of the inflamed and unduly sensitive parts.

The swollen condition of the mucous membrane and consequent constriction of the glottis manifestly give rise to the constant difficulty of breathing; and the temporary paroxysms of extreme dyspnœa are caused by muscular spasm incidentally or accidentally excited.

Passages. Vol. i., p. 705.

Thomas Watson alludes to an instance in which a fatal result ensued in twelve hours.[1]

Mr. Gray mentions the case of a man who was "admitted into St. George's Hospital complaining merely of sore throat. He walked into the hospital, and seemed in such good health that he would not have been admitted, but for the circumstance of his having come some distance from the country. About three hours after his admission, the house surgeon was summoned in all haste to see him, as he was said to be dying of suffocation. He went immediately, but found the patient quite dead. Post-mortem examination revealed all the evidences of laryngitis, supervening apparently upon inflammation of the pharynx; but it was especially remarked, that the chink of the glottis was not much narrowed from œdema. In this case there can be no doubt that death was produced by spasmodic contraction of the muscles of the glottis.[2]

In some instances, however, the malady runs a less rapid course, and the patient survives until the eighth or ninth day. In others, and these happily not a few, the inflammation subsides either spontaneously, or as the result of treatment. In such cases the effects may disappear almost altogether with comparative rapidity, or the malady may assume a chronic form.

Treatment.—The treatment requisite depends upon the severity of the malady, and the stage it may have reached. Measures which are urgently demanded in some cases are in others unnecessary, and even dangerous. And the mode of treatment that might be most efficacious at the onset of the malady, if adopted too late, may only hasten the fatal termination.

In the earlier stages, and in cases in which the symptoms are comparatively mild, perfect quiet in a warm moist atmosphere [pellets of ice allowed to melt in the mouth from time to time; a cold compress over the anterior portion of the neck], soothing inhalations either of simple or medicated steam or spray, and the administration of salines, with perhaps antimonials and tincture of aconite or some sedative, according to circumstances, constitute the treatment requisite. But in all cases careful watching is necessary; for dangerous symptoms may supervene at any time, and even almost suddenly.

In the more severe forms of the malady, similar but more energetic measures must be rigorously enforced. Soothing inhalations may still be advantageously employed, but their use must be more constant. Antimony and tincture of aconite in small but frequently repeated doses should be administered, especially in cases in which there is much general inflammatory fever.[1] Free mercurialization has been strongly advocated, but its efficacy appears doubtful; and much precious time may be lost before the system can be affected. General bloodletting, so highly lauded in past times in the treatment of this disease, may be resorted to in the earlier stages. But satisfactory evidence in favor of this proceeding is altogether wanting. Sir Thomas Watson says:—

> "When there is high inflammatory fever present, and the skin is hot, and the pulse firm and full, and the cheeks red, and the lips florid, you may bleed your patient with decision and advantage. But if his powers are beginning to sink under the poisonous influence of imperfectly aërated blood, if his skin be cold or even cool, his face pale or leaden, his lips blue, his pulse small and feeble, his mind wavering, you will do no good by bloodletting: nay, you will increase the debility which already exists, and hasten the fatal catastrophe."[2]

The instances, however, which Sir T. Watson quotes, tell as much against, as in favor of general bloodletting. And indeed it would appear that more air in the lungs is required, rather than less blood in the system. Local bloodletting by means of leeches to the neck or upper part of the chest, or cupping to the nape of the neck, may sometimes prove beneficial. So also may blisters or milder counter-irritants; but these should not be applied immediately over the larynx.

When the mucous membrane is so swollen as to impede respiration and swallowing to a serious extent, scarification by means of a sharp-pointed guarded bistoury, or some specially designed instrument, is often followed by speedy relief.

A somewhat remarkable case illustrating the effects of this method of treatment came under my observation in December, 1866. A gentleman residing in Essex, fancying he heard poachers in the neighborhood, got up in the middle of the night, went out carelessly dressed, and concealed himself for two or three hours in a ditch. The next morning he was seized with all the symptoms of intense laryngitis; and he died suffocated within eighteen

[2] Op. cit., p. 835.

hours. Three days afterwards the brother of this gentleman, depressed in spirits, and fatigued, and almost exhausted, was exposed for some time to cold and wet. In the evening he was attacked by symptoms similar to those from which his brother had suffered. The next morning I saw him in consultation with his medical attendant, Mr. Jordison, of South Ockenden. The soft palate, uvula, and pillars of the fauces were acutely inflamed, and very much swollen and œdematous. The epiglottis and aryteno-epiglottidean folds were in a similar condition. The patient's suffering was extreme; breathing was carried on with great difficulty; swallowing was impossible. I at once freely scarified the affected parts by a number of punctures and small incisions, and caused the patient to inhale the steam of hot water. A considerable quantity of serous or seropurulent exudation with some blood was discharged. In the course of half an hour the breathing was much relieved, and swallowing was accomplished without any great difficulty. The swelling of the parts rapidly subsided, and the next day, when I saw him again, the patient could breathe and swallow with comparative ease—indeed, almost naturally—but he still suffered from considerable general distress, and symptoms of pericarditis were recognized. Death took place twelve hours after my visit, or about sixty hours from the commencement of the attack. Post-mortem examination revealed the most intense inflammation of the whole pericardium I have ever seen. But the extent to which the faucial and laryngeal mucous membranes had recovered their natural condition and appearance was very remarkable.

Sir G. D. Gibb (following Dr. Horace Green) strongly advocates the application of a solution of nitrate of silver (three or four scruples to an ounce of water) in cases of acute laryngitis. The application may be made by means of a full bellied camel's-hair brush on a curved aluminium wire stem, or by "the laryngeal fluid pulverizer." "The effect of this proceeding is some considerable amount of burning heat, associated with comparatively little spasm, and sometimes dyspnœa, the last two persisting for may be a few seconds only. . . . The relief experienced, and the amelioration in the general symptoms, is observed in periods ranging from half an hour to four hours, and the dyspnœa subsides very speedily."[1]

If, as too often happens, the malady advances in spite of all such measures as those above suggested, or if the difficulty of breathing is too urgent to admit of their adoption, tracheotomy must be at once performed. In no class of cases probably is the value of tracheotomy as a life-saving operation more obvious and more pronounced. No definite rule can be laid down as to the period at which it may be desirable to operate. The surgeon must decide in each case when the proper moment has arrived, and must not hesitate to urge in the strongest terms the importance of every minute. There is far greater danger in delaying the operation too long, than in performing it unnecessarily early. The operation itself, if properly performed, is attended by little or no risk.[1] But it affords immediate relief from the direst suffering. It obviates altogether the recurrence of those frightful paroxysms of dyspnœa, in any one of which the patient may die suffocated. It affords perfect repose to the suffering parts, and saves them from the irritation of the hard-drawn breath. It thus allows opportunity for the subsidence of inflammatory action, and the absorption of effused material. It may not *cure*, but if performed in time, it certainly ensures a period of safety and freedom from distress, during which the cure may be effected by natural processes.[2] Further, in acute laryngitis the obstruction to respiration is, as a rule, confined to the larynx itself, and the parts below are rarely affected to any serious extent: the malady runs a rapid course, and under favorable circumstances subsides almost as quickly as it arises. Hence, not only is immediate relief almost absolutely certain, but there is little probability that the canula need be retained longer than a few days at the outside. While fully impressed with the danger of delay, the surgeon must nevertheless bear in mind that until the patient is actually dead it can never be too late to attempt the operation. And even if it should seem that the last breath has just been drawn, the operation should still be completed, and persevering efforts made to restore life by artificial respiration. Success has crowned such efforts in cases in which the general powers have not been too far exhausted by slow asphyxiation. [In the editor's practice he has restored respiration by insufflation through a catheter passed into an artificial opening into the trachea, made fully four minutes after apparent death. Other similar rescues have been reported.]

Chronic Catarrhal Laryngitis rarely occurs except as the result of one or more attacks of acute or subacute inflammation.

[1] On Diseases of the Throat and Windpipe, by G. D. Gibb, M.D., 2d edition, p. 196.

[1] See an essay by the present author: On Some of the Difficulties and Dangers of Tracheotomy, in the Practitioner, April, 1869.

[2] Out of 49 cases of tracheotomy for acute laryngitis of this kind which have come under my observation, or of which I have collected particulars, life was saved in 30, and death ensued in 19. In many of the fatal cases the operation was obviously performed too late; hence the result.

As such, however, it is a comparatively common affection. In this respect it differs remarkably from "Chronic Glandular Laryngitis" or "Follicular Disease of the Larynx," which, as a rule, is not preceded by any acute inflammatory symptoms, but on the contrary is chronic in character throughout its whole course.

Chronic catarrhal laryngitis is much more frequently met with among adult males than among females or children. This is due in great measure, no doubt, to the more constant exposure to vicissitudes of weather to which men are subject, as well as to the greater demands made upon their respiratory and vocal organs from the nature of their occupations. It often results in cases in which the acute symptoms have not been very severe ; or in which they have subsided so far as to permit the patients to resume, without immediate inconvenience, their usual habits before the actual structural lesions have been sufficiently repaired. Hence the necessity for continued rest, watchfulness, and judicious treatment during convalescence from acute catarrhal laryngitis, even though the symptoms may have been comparatively mild. It need scarcely be remarked that when once the chronic affection is established, and so long as it continues, the patient is especially liable to a recurrence of acute attacks, any one of which may be fraught with danger.

The *symptoms* of chronic catarrhal laryngitis are:—hoarseness, want of tone, or some other unnatural condition of the voice; a sense of effort during speaking (especially if at all prolonged), and of fatigue afterwards; frequent desire "to clear the throat;" and more or less frequent cough, accompanied by occasional but scanty expectoration of thick, grayish, opaque, or semipurulent mucus. A general sense of discomfort is sometimes experienced, but there is no pain in the part; nor is there any marked tenderness on pressure. Tranquil respiration is, as a rule, performed easily, and without the characteristic whistling or throttling sound emitted during inspiration in acute laryngitis. Forced respiration, however, is sometimes accompanied by unnatural sounds, which may be readily heard by means of a stethoscope placed over the larynx or trachea. The cough is no longer "tearing" and painful, nor harsh, ringing, and "brassy" as in the acute stages: though often hoarse, and somewhat sonorous, it is not distressing, and suffocative paroxysms very rarely if ever occur. Deglutition is easy and painless.

Thus it would appear that there is nothing absolutely distinctive in the symptoms of chronic catarrhal laryngitis; for very similar symptoms are associated with other totally different conditions to be hereafter discussed. Nevertheless, it is very important that a correct diagnosis should be made, inasmuch as the treatment requisite, as well as the probable issue, may differ very materially from what would be indicated in at any rate some of the other affections alluded to.

On *laryngoscopical inspection* the mucous membrane of the larynx is seen to be thickened and unnaturally red, and covered here and there by patches of grayish opaque mucus. The thickening and redness may be either more or less uniform, or irregular and much more pronounced in some parts than in others. In order of frequency the posterior aspect of the epiglottis, the aryteno-epiglottidean folds, the inter-arytenoid fold, the anterior aspect of the epiglottis, the false vocal cords, and the true vocal cords, are the parts usually affected. In general terms, the acute inflammatory attack is most frequently followed by chronic after-effects in those parts which are naturally most vascular, and most abundantly supplied with glandular structures. Ulcers are very rarely seen, but sometimes small superficial cicatrix-like patches may be observed; and occasionally even a dilated bloodvessel or two may be noticed ramifying in the mucous membrane.

The alteration of the voice does not bear any definite relation to the extent to which the true vocal cords are affected. There may be considerable hoarseness, or partial or even complete loss of voice, in cases in which the vocal cords themselves are found on examination to be almost or altogether healthy in appearance. In such cases the explanation may be due either to the swollen condition of the neighboring parts, which may mechanically prevent the due approximation and tension of the true vocal cords, or may deaden or modify the sound produced by their vibration; or it may be that the surrounding infiltration, or some other effect of the inflammatory process, may hamper or otherwise interfere with the necessary action of the muscles. Whatever may be the explanation in any particular case, laryngoscopy has amply proved (contrary to what was formerly supposed) that the voice may be more or less obviously altered in character, or impaired in power, although the true vocal cords retain their integrity and healthy appearance. The converse is also true. The vocal cords may be visibly affected to some extent in various different ways, as hereafter indicated, without any very serious detriment to the speaking, if not to the singing voice.

The *course and duration* of chronic catarrhal laryngitis vary greatly in different cases. Sometimes it subsides spontaneously in the course of two or three weeks or more. Sometimes, especially if neglected, it remains obstinately persistent; and more or less permanent thickening or hypertrophy (so called) of the mucous membrane results. As a general rule, however, it is amenable to treatment. In some cases of long standing, warty growths become developed. In others tracheal, bronchial, or pulmonary complications arise. In all cases there is great liability to fresh attacks of acute or subacute inflammation.

Treatment.—The treatment most likely to prove successful in simple catarrhal laryngitis, which has become chronic in character, depends somewhat upon the stage the malady may have reached, and the severity of the symptoms. It rarely happens, however, that any other than local measures are requisite, or indeed beneficial, except in so far as they may tend to the improvement of the general health and strength. But in all cases it is desirable, and in some absolutely necessary, to insist upon the importance of affording to the suffering parts as much rest, and as little excitement and irritation, as may be practicable. All unnecessary exertions of the vocal and respiratory organs must for a time be avoided. The most complete rest possible can only be ensured by tracheotomy: and sometimes resort to this operation may be advisable even in the absence of any very acute symptoms. [The writer of these notes is unable to endorse the foregoing recommendation of tracheotomy in this affection, unless it be demanded by urgent dyspnœa threatening suffocation.]

In the earlier stages, the warm soothing vapor inhalations, so beneficial during the period of acute inflammation, must be replaced by more or less frequently repeated applications of astringent solutions, either in the form of spray or by the brush. In a large proportion of cases the inhalation of the spray of weak solutions of alum, tannic acid, [sulphate of zinc, sulpho-carbolate of zinc], or perchloride of iron, or chloride of zinc four or five times a day—or even of common salt, chloride of ammonium, or chlorate of potash—is all that is necessary. Sometimes, however—and indeed I believe in all cases according to some authorities—it is better to resort at once to the application of a strong solution of nitrate of silver (ʒj to ℥j of water) by means of the brush, or sponge probang

In the more advanced stages, when the affection has become decidedly chronic in character, and all reasonable hope of spontaneous subsidence, or of improvement under milder treatment has passed away, the efficiency of the application of the nitrate of silver solution is most marked. The whole surface of the interior of the larynx may be wiped round with the brush; or by aid of the laryngoscope the application may be limited to those parts only which are especially affected. If the sponge is used, as originally recommended by Dr. Horace Green, precision of application is of course impossible [unless a small fragment of sponge, firmly secured to a proper holder, is employed]; but the spasmodic contraction excited may serve to squeeze from the sponge a considerable quantity of the solution, which may become diffused over the whole surface. But, as before stated, the brush is far preferable to the sponge. The application is easily made in accordance with the directions already given.

The spasmodic distress, sometimes though not always produced, very speedily subsides. The good effects are almost immediately perceptible, but are by no means transient. In some cases the application seems to act almost like a charm; and the voice, which before was painfully hoarse, is rendered at once comparatively natural in tone. The application should be repeated once daily, on alternate days, or less often, according to circumstances, until the cure is complete. At intervals between the applications frequent inhalations of the spray of solutions of common salt, chloride of ammonium, or alum may be recommended. Small blisters may sometimes be advantageously applied over the larynx; or counter-irritation may be kept up by means of the strong tincture of iodine.

In cases of very long standing, and especially in those in which the tracheal and bronchial mucous membranes are also affected by chronic catarrhal inflammation, inhalations of balsamic and terebinthinate vapors often prove very beneficial. Turpentine, tar, the balsams of Tolu, Peru, and Canada, or their alcoholic solutions, gum benzoin or benzoic acid, and other similar substances, may be mixed (singly or in combination) with hot water in an appropriate vessel, and the vapor may be inhaled from time to time. Dr. Symonds recommends that substances of this kind should be mixed with æther or pyro-acetic spirit in a wide-mouthed bottle, from which the inhalation may be made.[1] Another method consists in keeping the atmosphere of the room, in which the patient may be, constantly impregnated with the remedial vapors, either by heating portions of the balsamic substances over a spirit lamp, or by putting them upon hot coals. This method is especially recommended by Trousseau and Pidoux, who state that by its persevering adoption cases of chronic laryngitis have been cured which had not been benefited by interrupted inhalations.[1] The same authors also refer to the good effects sometimes produced by the empyreumatic oil of burning paper ("l'huile de papier"), and recommend the inhalation of the smoke of cigarettes of paper, either plain or imbued with some arsenical or other medicinal solution.[2]

---

[1] The following formulæ are given: Æther ℥j, benzoic acid ʒiv, Peruvian balsam ℥ij, mix. 2. Pyro-acetic spirit ℥ss, æther ℥ss, benzoic acid ʒiv, balsam of Peru ℥ij; mix. 3. Æther ℥ss, spirits of turpentine ℥ss, benzoic acid ʒiv; balsam of Tolu ʒij; mix. 4. Æther ʒvj, pyro-acetic acid ʒij; mix. The warmth of the hand is sufficient for volatilizing these mixtures.—Therapeutical Memoranda, by J. A. Symonds, M.D., British Medical Journal, May, 1868, p. 448.

Tar water may be inhaled in the form of spray; so also may weak solutions of chloride of zinc, nitrate of silver, etc. But these saline solutions appear to be less efficacious in cases of the class now under discussion than in those which are more recent, and in which the morbid condition of the mucous membrane is less extensive, and less confirmed in character.

Internal remedies sometimes prove useful, especially such as are indicated in catarrhal affections of the respiratory mucous membranes generally, as for example, decoction of senega with ammonia, the various balsams, chloride of ammonium with tonics, etc.

[The habitual use of cold compresses at night is often very advantageous. It is sometimes advisable to bathe the anterior portion of the neck with dilute spirit of turpentine, or spirit of camphor, before applying the compress.]

Men who are subject to catarrhal and other chronic affections of the larynx should wear their beards; and women should be advised to take due precaution for the protection of their necks, especially when they are exposed to cold, or to vicissitudes of temperature.

Chronic Glandular Laryngitis. Follicular Disease of the Larynx. Dysphonia Clericorum.

Chronic Glandular Laryngitis is a comparatively common affection.[3] It is most frequently, but by no means solely, met with among those who are subject from time to time to continuous exertion of the voice, as clergymen, barristers, singers, and others. It essentially consists in more or less general enlargement and hypertrophy of the glandules and follicles of the laryngeal mucous membrane, the result of an inflammatory condition which usually commences very insidiously, and always progresses very slowly. It is often, but not invariably, associated with a similar affection of the faucial, nasopharyngeal, and pharyngeal mucous membranes.

The most frequent cause probably is, as already indicated, continuous exertion of the voice. It is obvious that in prolonged speaking, reading, or singing, the demands made upon the vocal organs are not only greater than during ordinary conversation, but also in some degree different. In ordinary conversation the parts are subject to no great strain; and more or less frequent intervals of rest are afforded, during which the mucous membrane can recover its normal condition. But in the continuous and strong exertion of the voice constantly made by public speakers and singers, the mucous membrane is especially liable to become irritated by the forcible contact, and rapid passage over it, of cold dry air drawn in at each inspiration through the mouth, and not warmed and moistened by passing through the nasal fossæ. To allay the irritation and mitigate the dryness thus produced, the mucous follicles are stimulated to increased activity, and for a time are able to secrete a sufficient quantity of mucus for the lubrication of the surface. Ultimately they are liable to become inflamed and hypertrophied. Further, it is worthy of note that the mucous membrane covering the arytenoid cartilages, and immediately adjoining parts, is more rich in glandular structures than any other portion of the laryngeal mucous membrane. Now this part is constantly subject to a very great extent of motion, and also, perhaps, to considerable strain, during forced vocalization. And thus its glands are especially liable to be stimulated to increased activity; and the morbid condition under discussion may eventuate.

It is important to bear in mind, however, that chronic glandular laryngitis may, and indeed often does, occur in persons who have not been subject to any such continuous vocal exertions as those above referred to. In such cases exposure to cold and fog (especially if there is any obstruction of the nose), and the constant inspiration of air charged with irritating fumes or particles, appear to be the most frequent causes. Gibb states that he has seen this malady "in a very exaggerated form in photographers, and persons much exposed to the fumes of acrid chemicals in confined chambers, and its obstinacy in them is something quite remarkable."[1] It is possible also that some constitutional tendency may favor the development of the malady. Indeed, Trousseau, Chomel, De Mussy, and others attribute its origin to the "herpetic diathesis."

---

[1] Traité de Thérapeutique, par Trousseau et Pidoux. Vol. ii., p. 840. Paris, 1869.

[2] Ibid., vol. i., p. 172.

[3] This affection appears to have been first accurately and fully described by Dr. Horace Green, of New York, to whom also is due the credit of having especially taught and insisted upon the proper method of treating this and other affections of the larynx by the topical application of solutions of nitrate of silver, etc. See a Treatise on Diseases of the Air Passages, by Horace Green, M.D., New York, 1846.

The *symptoms* are: alteration of the voice, and sense of effort in sustaining it—these are by far the most prominent and constant symptoms; more or less discomfort about the larynx, never amounting to pain, but occasionally troublesome; dryness, and sometimes a sense of heat about the throat; and constant desire to clear the throat by "hemming" and "hawking." There is little or no regular cough; and the expectoration which sometimes occurs, is slight, scanty, and mixed with saliva. There is neither difficulty in swallowing, nor tenderness upon pressure over the larynx. There are no definite constitutional symptoms; but the general health and spirits of the patient are often observed to be more or less depressed.

The alteration in the voice depends upon the swollen condition of the arytenoid mucous membrane, which prevents the free movement of the cartilages, and thereby the necessary approximation of the vocal cords. The character of the voice varies somewhat. In the earlier stages it is simply wanting in clearness, and tone, and general reliability. In the later stages it becomes disagreeably harsh, husky, and hoarse. Sometimes it fails altogether, and the patient speaks in a husky whisper. As a general rule the alteration in the voice is most pronounced in the early morning, before the vocal organs have been at all exercised, and again in the evening, or after any considerable exertion of the voice, when the parts have become fatigued. Sometimes the patient will feel that he is able to carry on ordinary conversation with ease; but directly he begins to read or speak continuously in a loud voice he finds it impossible to proceed; or he only does so with great difficulty, sense of effort, and subsequent fatigue.

On inspection, the mucous membrane of the fauces and back of the throat is usually seen to present a more or less raw and irregularly granulated appearance; and the enlarged glandules, each, (it may be) surrounded by a little halo of undue redness, may be recognized studding the surface. *Laryngoscopical examination* shows that the mucous membrane of the larynx is similarly affected; and in some cases, as already indicated, the malady is confined to the larynx. The parts most frequently and most obviously affected are, as might be expected, those in which the glandules are most abundant. These parts are the mucous membrane covering the arytenoid cartilages, the inter-arytenoid folds, the base of the epiglottis, and the ventricles and sacculi of the larynx. In cases of long standing, points of ulceration may sometimes be observed, especially about the base of the epiglottis. In others the glandules appear to be not simply enlarged, but distended with opaque yellowish material.

The mucous membrane covering the vocal cords is very thin, and contains very few, if any, glandules. It is very rarely, therefore, observed to be affected in this malady. It occasionally presents, however, isolated granulations which might possibly be mistaken for enlarged glandules. Such a condition is described by Türck under the name of *Chorditis Tuberosa*.[1]

The *course* of chronic glandular laryngitis is very tedious, and its *duration* very long, often extending over months or even years. It is not readily amenable to treatment; but by perseverance much good may generally be effected. Certain forms of new growth occasionally met with in the larynx may not improbably owe their origin to the localization of this or some allied affection of the mucous glandules.

Treatment.—The method of treatment, which experience has shown to be the most effectual, consists in the application by the brush of solutions of nitrate of silver or perchloride of iron, at intervals varied in frequency according to circumstances. The nitrate of silver, I believe, is, as a rule, the best application. Sulphate of zinc, sulphate of copper, and tincture of iodine,[2] have also been recommended, and indeed it may be stated that it is often well to vary the application. That which answers perfectly in one case, or at one period, proves less efficacious in others, or at other periods and under changed conditions in the course of the same case. Any points of ulceration tha may be seen should be touched by mean of the probe with solid nitrate of silver Between such applications spray shoul be inhaled at frequent intervals durin the day. The best solutions for the pu pose are those of common salt, chlorid of ammonium [biborate of sodium, b carbonate of sodium, chlorate of pota sium], iodide of potassium, and in som cases alum, or weak solutions of perchl ride of iron. Certain mineral water especially such as contain the sulphides of sodium or calcium, have also been strongly recommended, as well as artificial solutions of sulphurous acid.

A method of treatment, which appears to be especially useful in this form of laryngeal disease, consists in slowly sucking medicated lozenges. The precise and careful observations of Fournié[1] prove (contrary perhaps to what might be expected) that certain portions of liquids swallowed, especially if swallowed slowly, or allowed almost insensibly to find their way down the pharynx, may become applied to the upper part of the larynx, and even diffuse themselves to some extent over its internal surface. The lozenges that appear to prove most useful are those containing chloride of ammonium, with or without cayenne, and the "red-gum lozenges," made by Messrs. Squire.

[These lozenges often offend the stomach, producing mawkishness, loss of appetite, and indigestion, on account of the sugar in their composition.]

In this, as in other chronic laryngeal affections, the beard should be worn; and all due general precautions should be taken; for, as need scarcely be stated, an attack of ordinary catarrhal laryngitis may be readily excited.

Tonics and other constitutional remedies, varied according to circumstances, often prove very beneficial. It is especially necessary to reassure the mind of the patient; for he is but too often depressed in spirits, and apt to think his malady far more serious than it really is.

PHTHISICAL LARYNGITIS.

The larynx is found to be more or less seriously affected in a very large proportion of cases of tubercular phthisis.[2] In some cases the earliest recognizable indications of the commencement of the malady appear in the larynx. In others, when the malady is fully established, the laryngeal symptoms are the chief if not the only source of the distress from which the patient suffers. In others again, the condition of the larynx gives rise to effects which may to a considerable extent mask or simulate the physical signs and symptoms of incipient, and even of advanced pulmonary disease; and thus the diagnosis may be rendered very difficult.[1] Hence the importance of making careful laryngoscopical examinations in all cases of suspected phthisis, and especially in such as present indications of laryngeal mischief.[2] There can be no doubt, I think, that most of the so-called "cures of consumption" said to have been effected by local applications and inhalations (in so far as the accounts given may be considered reliable) have occurred in cases in which the larynx has been principally, if not solely, affected.

In the very earliest stages, the [subjective] *symptoms* of phthisical laryngitis are simply weakness, uncertainty, slight huskiness, and occasional failure of the voice, together with a more or less constant desire to clear the throat of the thick whitish mucus which accumulates from time to time. [The earliest objective symptoms are pallor, and a thickening of the structures about the supra-arytenoid cartilages, giving the aryteno-epiglottic folds a peculiar pyriform or clubbed appearance at this point, due, as determined by microscopic inspection, to accumulation of *lymphoid* or *adenoid* elements.] On *laryngoscopical examination* the mucous membrane is seen to present a peculiar dotted granular appearance, which is usually first, and, as a rule, most conspicuously manifest on the posterior aspect of the epiglottis. This appearance is probably associated with the earliest deposit of tubercular material taking place in minute quantities at many distinct points. Somewhat later, the mucous membrane covering the arytenoid cartilages, and the aryteno-epiglottidean and inter-arytenoidean folds are affected, and sometimes present granulation-like elevations. At the same time more or less thickening of the mucous membrane may be observed. This thickening is an important and almost characteristic feature. It is to some extent due to increased deposit of tubercular material as well as to inflammatory infiltration. The false and true vocal cords, as a rule, become implicated only at a still later period, and usually on one side first. The false vocal cords partake of the general thickening, and often hide the true vocal cords; and these latter lose their clearness and brilliancy. As the malady advances, ulceration occurs in one part or other, and usually first on the posterior aspect and lower part of the epiglottis. At or about this period the voice becomes hoarse; breathing is carried on with a sense of effort, and sometimes with difficulty and pain; the cough (before rare, and indeed often little more than a more or less frequent "hemming") becomes constant, and sometimes painful; the expectoration is increased in quantity, and somewhat changed in character, becoming yellowish, and occasionally slightly streaked with blood; and sometimes, according to the position of the ulceration, there is pain in swallowing. So long as the ulceration is confined to the posterior surface of the epiglottis, swallowing is easy; but when the edges, upper border, and anterior surface of the epiglottis, and especially the glosso-epiglottidean folds are implicated, swallowing becomes painful. The ulcerative process, after it has once commenced, goes on; slowly it may be, but surely nevertheless. It extends gradually, not only superficially, but also in depth. Fresh centres of ulceration often appear, and by and by the deeper structures, areolar tissue, cartilages, etc., become involved, and in turn destroyed. Inflammatory swelling and œdema of the surrounding parts supervene. When the perichondrium is attacked the subjacent cartilage may either share in the ulceration and become gradually eaten away, as frequently happens to a greater or less extent with the epiglottis; or it may become partially or wholly necrotic, and may give rise to the formation of an abscess, in the midst of which the necrosed portions may remain for a longer or shorter period. The arytenoid cartilages appear to be most frequently and earliest liable to become necrotic; next, the cricoid cartilage. The thyroid is comparatively rarely affected in this way. It would seem that before becoming necrosed the cartilage generally undergoes a process of calcification. Concomitantly with these morbid changes, the expectoration becomes abundant and purulent; the voice is lost; breathing becomes more constantly difficult and painful; and from time to time the most distressing paroxysms of spasmodic dyspnœa may come on. Under such circumstances laryngoscopical examination is often very difficult, not only on account of the general state of the patient and the hyperæsthetic condition of the pharynx commonly existing in such cases, but also on account of the malposition, deformity, and swelling of the epiglottis resulting from the disease, and the abundant muco-purulent secretion by which the view is often completely obscured. When, however, a view is obtained, some idea may be formed as to the character and extent of the ulceration and destruction of parts that may have taken place. And it will usually be observed that the epiglottis and the posterior and upper parts of the larynx have suffered to the greatest extent; and that the ulcers are surrounded by more or less considerable thickening of the surrounding parts. Sometimes even projecting points of necrosed cartilage may be seen exposed, or bathed in pus. Post-mortem examination (the opportunity for which as a rule speedily occurs) confirms the correctness of such observations, as well as the inferences drawn from them.

[1] Étude pratique sur le Laryngoscope et sur l'application des remèdes topiques dans les voies respiratoires. Par le docteur Édouard Fournié, Paris, 1863. Also L'Union médicale, 5 fév., 1863. p. 248.

[1] Louis states that he found ulceration of the larynx in 63 out of 193 cases of phthisis which he examined. Researches on Phthisis. By P. C. A. Louis, M.D. Sydenham Soc. Trans., Lond., 1844. According to the records of post-mortem examinations made at Guy's Hospital during the last six years, it appears that the larynx was affected in 47 out of 145 cases. The epiglottis is considered as part of the larynx; some cases, therefore, are included in these numbers in which the epiglottis only was affected.

[1] Cases occur from time to time in which affections of the larynx and trachea so closely simulate pulmonary disease that the patients are falsely supposed to be in a state of "hopeless consumption." On this subject see especially Dr. Scott Alison, On Morbid Conditions of the Throat in their Relation to Pulmonary Consumption, p. 10 et seq. London, 1869.

[2] See the excellent remarks of Dr. Marcet on the value of the Laryngoscope in the diagnosis of phthisis, in his work on Diseases of the Larynx. Op. cit. p. 80 et seq.

In some cases the ulcerative process does not commence so early, nor extend so deeply as thus stated; and it may even happen that healing may take place. In certain exceptional cases under favorable circumstances the process of healing may be watched from time to time by aid of the laryngoscope, as I know from my own observation, as well as from the statements of others. And further, it is by no means very unusual to find on post-mortem examination the cicatrices of healed ulcers in the larynges of those who have died of phthisis. In other cases thickening followed by softening, and it may be by subsequent absorption, without definite ulceration, may be observed to take place in localized patches. During this process there is abundant expectoration of thick whitish mucus. In all such cases the symptoms are proportionately less severe and the progress of the malady is much slower than in cases of the class first described. Post-mortem examination not unfrequently shows more or less pronounced affection of the larynx in cases in which during life there have been scarcely any laryngeal symptoms beyond slight hoarseness, or some other alteration of the voice.

The *course and duration* of phthisical laryngitis vary greatly, not only with the special character and type of the local affection, but also still more notably with the degree of development and severity attained by the pulmonary disease, and the general morbid conditions at the period at which the larynx first begins to suffer. Thus, in the first place, as already stated, the disease may begin in the larynx, and there may be no indications whatever of the presence of tubercle in any other part. In the second place, the larynx may appear to become affected almost simultaneously with the lungs, and the disease in the two parts may go on almost *pari passu*. In the third place, the affection of the larynx may be consecutive to advanced disease and disorganization of the lungs, and may even upervene, as it were, almost at the very ermination of the case.

In cases belonging to the first class inicated, the progress may be comparaively rapid, and the patient may die sphyxiated from the results of the laryneal disease alone; or exhaustion may ome on gradually. More frequently, owever, the progress of the malady is ow; and sometimes apparent or even tual recovery of temporary character ay take place. But sooner or later the alady appears afresh, often with greatly creased severity; and all the signs and mptoms of pulmonary mischief become anifest.

[Acute, and apparently primary, tuerculosis of the larynx, is almost sure be followed, within two or three weeks, y acute tuberculosis of the lungs; with fatal issue within from six to twelve eeks in most instances, and rarely reachng six months or longer.]

In cases belonging to the second and hird classes indicated, the downward proress is almost invariably more or less apid. It too often happens that the paient seems prematurely hurried to his nd by the difficulty of breathing and wallowing, and all the various sources of distress associated with the laryngeal complications of his fatal, but otherwise almost painless malady.

Treatment.—It would be altogether out of place to discuss in these pages the constitutional treatment requisite in tubercular affections generally, and in pulmonary phthisis especially. Suffice it to say, that similar constitutional treatment is indicated in phthisical laryngitis. It must ever be borne in mind that this malady is but a local expression, so to speak, of a general morbid tendency, to modify which all possible endeavors must be made. At the same time, the part affected is so important, and the associated danger and suffering may be so great, that no measures must be neglected by means of which the symptoms may be alleviated and the danger averted, if only for a time. Experience amply shows that in such respect ocal treatment is often very beneficial.

In the earliest stages it does not appear hat any topical applications are likely to e efficacious in arresting the malady; ut rest to the parts affected, and avoidnce of all sources of irritation, may fford opportunity for general improveent under constitutional treatment. But when once ulceration has commenced the need for local treatment arises, and indeed may become most urgent. Soothing inhalations of the steam from hot water, in which hemlock, hops, stramonium, or opium have been infused, often afford much comfort. So also do spray inhalations of anodyne solutions. Similar solutions applied by the brush are sometimes very useful. They may not cure, but they give the temporary relief the sufferer so often and so anxiously looks for. An excellent formula quoted from Krishaber[1] is as follows: Extract of opium and extract of belladonna, equal parts, dissolved in forty parts of cherry-laurel water. The beneficial effects of this application, although transient, are immediate and almost invariable. [Local applications of carbolic acid and compound iodine liquor, diluted in five or more parts of water or glycerine, are beneficial in many cases.]

Small ulcers may often be advantageously touched with the solid nitrate of silver: a protective covering from the irritating influence of the passing breath is thus formed for them. [Iodoform in powder, or in etherial solution, is often useful.] But the application of the solution of nitrate of silver to the mucous membrane generally, appears in many cases to do harm rather than good. Marcet recommends repeated scarification of the thickened parts of the mucous membrane.[2]

In cases in which the dyspnœa is great, and clearly dependent upon the condition of the larynx—in cases especially in which there is great difficulty in swallowing, and consequent danger of death from want of sufficient nourishment—tracheotomy should be performed without hesitation. The existence of even extensive disease in the lungs cannot be regarded as forbidding the adoption of this certain mode of relief from those symptoms which alone are distressing. Death from pulmonary phthisis is always easy; but death from laryngeal phthisis is preceded and attended by the direst suffering. Tracheotomy cannot ward off the one mode of death; but it is powerful to rob the other of its horrors. I have seen such immediate and such complete relief afforded by the operation in several cases, about the hopeless character of which there could be no doubt, that I should never hesitate to repeat it in similar cases, feeling certain that though life may not be saved, it may be prolonged, and suffering may assuredly be diminished during the remaining days. Further, it may be added, that cases do occur from time to time in which the whole

---

[2] Op. cit., p. 674.

disease is in the larynx, although the accompanying symptoms and wasting closely resemble those of general phthisis, and the physical signs are so far obscured as to afford no reliable indications. Three cases have come under my observation, in each of which the patient had been pronounced to be dying of "hopeless consumption." In each of these, more or less complete recovery speedily followed the performance of tracheotomy.

Syphilitic Laryngitis.

Syphilitic affections of the larynx are comparatively common.[1] They vary in character and importance with the period of the disease at which they arise, and also with the general health and condition of the patient.

During the *Secondary Stages* of Syphilis the mucous membrane of the larynx may be affected in a manner corresponding with the cutaneous eruption present; or it may become ulcerated, either independently, or in direct continuity with the characteristic ulceration of the soft palate, fauces, and pharynx, which so commonly occurs. The actual existence of the several conditions referred to has been fully established in very many cases, and may as a rule be readily recognized, by aid of the laryngoscope.[2] Without such aid the precise condition of the larynx in any particular case can only be inferred from the symptoms; and a considerable degree of uncertainty necessarily attends the diagnosis.[3]

Erythema of the laryngeal mucous membrane often occurs in association with syphilitic roseola of the skin. It may either extend from the fauces to the epiglottis and upper part of the larynx, and thence spread over the whole mucous surface; or it may appear in isolated, and more or less well defined patches. The mucous membrane in the parts affected presents on laryngoscopical inspection a dusky red or even purplish hue, and it may be, a slightly elevated or swollen appearance.

More distinctly elevated and better defined patches (*mucous patches*) are sometimes seen in association with papular, squamous, and especially with tubercular affections of the skin.

The *symptoms* accompanying these comparatively simple conditions are not, as a rule, severe; nor are the results likely to prove serious. The voice is generally altered to some extent: it may become weak, wanting in tone, husky, or somewhat hoarse. But there is neither dyspnœa nor troublesome cough; nor is there local pain, nor any difficulty in swallowing that can be referred to the affection of the larynx.

The peculiar character of the voice so constantly noticed in secondary syphilis, and by some considered almost pathognomonic, would appear to depend in great measure upon one or other of the conditions of the larynx thus described, rather than upon the concomitant affection of the palate, fauces, and nasopharyngeal mucous membrane, the existence of which is more readily obvious, and to which alone the explanation is commonly attributed. Such, at any rate, is the conclusion indicated by the results of my own observations, as well as by those of others. It must be borne in mind that an affection of the mucous membrane of the larynx which is only superficial, and to the eye of the observer appears slight, may nevertheless, directly or indirectly, hamper to a considerable extent the movements necessary for the production of the natural voice.

It sometimes happens that laryngeal symptoms, similar in character to those just described, and associated with similar laryngoscopical appearances, arise either gradually, or almost suddenly, five or six months after the commencement o the malady, and after all obvious affec tions of the fauces and pharynx hav subsided.

Syphilitic ulceration, as already stated may extend from the fauces and pharyn to the larynx. But it very rarely does s during the secondary stages, except i cases in which the general health an strength are much broken down, or i which there has been continuous or fr quent exposure, during the course of th malady, to the ordinary causes of acu laryngitis.

Occasionally small isolated spots superficial ulceration, similar to tho often observed in the mouth, appear the laryngeal mucous membrane.

During the *Tertiary Stages* of syphi the larynx is frequently affected in way or other, and in many cases to a very serious extent.

---

[1] According to my own experience, a very large proportion (from thirty to forty per cent.) of the cases of laryngeal disease met with in hospital practice, among the surgical out-patients, are of syphilitic origin. In private practice the proportion is very much smaller, but still considerable.

[2] On this subject, see especially the brochure of M. Dance, Sur les éruptions du Larynx dans la période secondaire de la Syphilis. Paris, 1864.

[3] Gerhardt and Roth state that in eight out of fifty-four cases of secondary syphilis under observation in Würzburg Hospital, the hoarseness was produced by mucous patches or condylomata of the larynx, which could be distinctly seen by aid of the laryngoscope. Arch. für path. Anat., Bd. xxi., Heft 1.

Papulo-tubercular Elevations of the Mucous Membrane are by no means rare. They vary in size, and also in situation. In some instances they simulate warty growths of more innocent origin; in others they more or less closely resemble the condylomata met with on other mucous surfaces.[1] Sometimes these elevations subside under appropriate treatment, or perhaps spontaneously. In rare instances they increase to such size as to necessitate removal by operation. Sometimes they ulcerate and form the starting points of ulcerations, such as are described in the next paragraph. They have been observed on the false and on the true vocal cords, as well as on various other parts of the laryngeal mucous membrane. The chief *symptoms* noticed are hoarseness, or some other marked alteration of the voice, and sometimes occasional fits of dyspnœa.

Tertiary Ulcerations of the larynx are comparatively common. They may commence either superficially in the mucous membrane, and thence penetrate to the subjacent structures; or they may result from the effects of some more deeply seated affection—as for example softening down of gummatous deposits in the submucous tissue, or perichondritis or chondritis—followed by the formation of abscess. They may occur singly, and in any part; usually, however, several spots are attacked, either simultaneously or one after another. The epiglottis is generally affected first, and in a large proportion of cases is the part most extensively destroyed. Sometimes its edges are gradually eaten away; sometimes its substance early becomes perforated, and the perforation extends until the edges are reached. In such cases semi-detached portions, flapping loosely, occasionally give rise to much embarrassment. The false and true vocal cords are often affected—in some cases by comparatively superficial, but in most by deeply penetrating ulceration. The mucous membrane covering the arytenoid cartilages, and the posterior part of the larynx generally, is comparatively less frequently and less early attacked by syphilitic than by phthisical ulceration; but it is liable to become involved sooner or later. The cartilages (and especially the arytenoids) may become carious or necrotic, as the result either of deep extension of ulceration commencing in the mucous membrane, or of perichondritis arising independently of any such superficial affection. Portions of dead cartilage may become detached, and acting as foreign bodies, may give rise to the most serious symptoms; or they may be expectorated, or removed by operation; or they may remain at any rate partially fixed, and in such case may become the foci of abscesses, and the excitants from time to time of the most dangerous paroxysms of spasmodic dyspnœa.

The *symptoms* vary according to the extent of the ulceration and the part especially affected. There is invariably marked alteration of the voice, sometimes hoarseness, sometimes complete aphonia, and sometimes one or other of the various intermediate conditions which are readily recognizable but difficult to describe or name. There may or may not be dyspnœa; and the dyspnœa, if present, may be slight, or of the most distressing character. In some instances, and especially in those in which the cartilages are affected, there may be occasional attacks of severe dyspnœa, with intervening periods of comparative or even complete ease; and sometimes suffocative spasm of the larynx may occur.

Two or three years ago, a patient (in the Venereal Ward in Guy's Hospital) who had suffered from occasional and slight but evanescent attacks of dyspnœa, was suddenly seized with such urgent and distressing difficulty of breathing that he rushed from the ward to seek help. He reached the bottom of the stairs, and then fell dead from suffocation. On post-mortem examination, a detached portion of necrosed cartilage was found in the glottis.

It is well to bear in mind, therefore, that in such cases dyspnœa of the most dangerous character may supervene suddenly, and almost without warning. Indeed, it may be asserted that patients suffering from severe tertiary affections of the larynx require the most careful watching, for danger may arise at any moment. In some cases there is difficulty in swallowing; and often more difficulty in swallowing fluids than solids. The former (on account of the condition of the epiglottis) are more liable than the latter to "go down the wrong way." But the slight degree of difficulty, and the absence of all pain in swallowing, sometimes observed in certain exceptional cases of this kind, in which the epiglottis has been even extensively destroyed, are very remarkable.

The *course and duration* of these tertiary affections of the larynx, as may be readily understood, vary greatly. In some cases, under appropriate treatment, cicatrization may take place; but in such it constantly happens that very serious deformities of the parts result either from the loss of substance, or from the subsequent contraction of the cicatrices that may have occurred. The voice is, as a rule, permanently impaired; and breathing and swallowing may be rendered more or less difficult. Attacks of acute laryngitis, attended by more or less spasm, are liable to be excited by comparatively slight causes, and may lead to a fatal result if timely relief is not afforded, or if the safety of the patient has not been previously secured by the performance of tracheotomy.

---

[1] M. Cusco has especially called attention to growths of this description, and to their syphilitic origin (see M. Dance, op. cit.). His observations accord with those of Türck and other observers, and are confirmed by my own experience.

The *general diagnosis* of syphilitic affections of the larynx is not often difficult. The history of the case, and the presence of the syphilitic cachexia, together with the coexistence of some more unmistakable signs or symptoms (such as ulcers or cicatrices about the palate and fauces, cutaneous eruptions, nodes on the tibiæ, etc.) generally serve to indicate the nature of the malady.

But beyond the general indications afforded by the history of the case, and by the presence or absence of other local affections of syphilitic origin, certain special indications may be obtained, and the diagnosis may often be clearly established, by aid of the laryngoscope.

The dusky hue and patchy appearance of syphilitic erythema of the larynx differ notably from the bright diffused redness of simple catarrhal inflammation; and the papules, flattened tubercular elevations of surface, and condylomata of syphilis can hardly be mistaken for the enlarged mucous follicles of glandular laryngitis—still less for the dotted, granular appearances presented in the earlier stages of laryngeal phthisis. There may, however, be considerable difficulty in distinguishing between a syphilitic tubercle or condyloma beginning to ulcerate, and a small epithelioma, especially if situated on the posterior wall of the larynx. Such difficulty has arisen in more than one instance under my observation. In any doubtful case it is well to try the experiment of "specific" treatment before expressing any decided opinion. Antisyphilitic remedies and local treatment will almost certainly effect a cure in the one case; and in the other, though necessarily useless, they cannot do any great amount of harm.

The deep and extensive ulceration of the more advanced stages of syphilitic disease of the larynx not only gives rise to symptoms, but on laryngoscopical inspection may present appearances, which more or less closely resemble those of phthisical disease on the one hand, and epithelioma on the other. It may not be easy, but it is always important to determine accurately the nature of the malady, as well as the extent of the mischief. For, as need scarcely be stated, the treatment which is requisite and likely to prove more or less successful in cases of syphilitic origin, might be absolutely injurious in those associated with phthisis, and altogether useless, or perhaps worse than useless, in epitheliomatous disease. The prognosis also must obviously depend in great measure upon the satisfactory determination of the origin of the local affection.

The chief distinctive features presented by syphilitic, phthisical, and epitheliomatous ulceration of the larynx may be stated as follows.

Syphilitic ulceration usually attacks the epiglottis first. It extends rapidly, and is emphatically destructive in its progress. It involves the submucous tissues at a comparatively early period; and thus the whole thickness of the epiglottis may speedily become perforated, or some other part of the larynx may suffer corresponding destruction of substance. It is not, as a rule, surrounded by any marked or extensive thickening; but its edges are often more or less swollen, and red. Such apparent or real thickening as there may be generally attends rather than precedes the ulcerative process. The accompanying expectoration is thick, tenacious, and yellow or yellowish green in color.

Phthisical ulceration usually commences in the mucous membrane covering the upper and anterior parts of the arytenoid cartilages. The posterior aspect of the epiglottis may often be seen at the same time free from ulceration, but presenting the dotted granular appearance already described. It is almost invariably preceded as well as always attended by marked and characteristic thickening. It progresses comparatively slowly; and, as a rule, does not penetrate at an early period to the deeper structures. When it attacks the epiglottis, the edges present an irregular, somewhat worm-eaten and grayish appearance. The accompanying expectoration is generally more frothy and thinner, and more mucopurulent in character than in syphilitic ulceration and much more abundant than in epithe lioma.

Epitheliomatous ulceration of the laryn in a very large proportion of cases con mences on the pharyngeal aspect of th mucous membrane covering the arytenoi or cricoid cartilages, and comparativel rarely in the interior of the larynx. It associated with very considerable and i regular thickening, due to the develo ment and increase of the new growt Its surface presents a dirty grayish a pearance, and its edges are elevated. progresses very slowly. The accompan ing expectoration, at any rate during t earlier stages, is scanty, thin, and often more or less sanious in character. In the advanced stages it becomes abundant, more or less purulent, and sometimes tinged with blood.

The other local and constitutional signs and symptoms, which in syphilitic and phthisical cases may aid the diagnosis, are altogether wanting in cases in which the laryngeal ulceration is simply epitheliomatous in origin.

Lupous, and other strumous ulcerations of the larynx which cannot, strictly speaking, be classed as phthisical, sometimes occur,[1] and are with difficulty distinguished from those of syphilitic origin. In some cases of the kind that have come under my observation, it has seemed that the affection has probably been due to congenital syphilis. The age of the patient, the history of the case, and the presence or absence of other local or general indications, afford the best guides in the diagnosis.

Treatment.—In syphilitic laryngitis, local as well as constitutional treatment is very often necessary, and in the more severe forms is urgently—nay, imperatively demanded.

The comparatively slight affections which so commonly occur during the secondary stages of the malady, and in which there is simply diffused or patchy erythema of the mucous membrane with but little swelling, as a rule, subside under constitutional treatment. But all unnecessary exertion of the voice, and especially exposure to cold and wet, should be sedulously avoided. Mercury in one form or other is the only remedy upon which any reliance can be placed; and the appearance of laryngeal symptoms may generally be accepted as an indication that it is desirable to get the system under the influence of this drug as speedily as may be practicable and safe. The use of the calomel vapor bath may be especially recommended in such cases, inasmuch as beyond its general efficiency it affords special facility for the occasional inhalation, and thereby the local application of the mercurial vapor. The value of such inhalation, however, is more pronounced in cases in which ulceration has commenced.

Secondary ulcerations of the laryngeal mucous membrane (whether in continuity with others about the fauces or pharynx, or appearing independently) may often be advantageously treated by local applications. But such applications must be regarded simply as adjuvants to the general treatment indicated, and not as in any measure rendering such general treatment unnecessary. The frequent inhalation of the spray of weak solutions of perchloride of mercury with chloride of ammonium, or of sulphate of copper, very often appears to be beneficial. In some cases the insufflation of calomel, or an occasional inhalation of the vapor of calomel, may be recommended. In other cases the application of solid nitrate of silver or sulphate of copper, from time to time, to the ulcerated surface does good. If there is much irritability, however, the inhalation of warm soothing vapors, or the spray of anodyne solutions, is for a time preferable.

Syphilitic affections of the larynx occurring during the tertiary stages of the malady almost invariably require the administration of iodide of potassium in full doses (gr. xx to gr. xxx) three or four times a day. In some cases the addition of iodine may be useful. In others, iodide of iron and tonics generally are indicated. Local measures are very often necessary in conjunction with the constitutional treatment indicated, and in all cases may do much to aid the cure. Condylomatous and papillary elevations of the surface may be touched daily, or less frequently, with the solid nitrate of silver. In cases in which ulceration has occurred, inhalations of the vapor of iodine, or of the spray of solutions of iodide of potassium and iodine, are very useful. If the ulcers are comparatively superficial, the application of solid sulphate of copper daily, or twice daily, often proves beneficial. If the ulcerated surface is extensive, a saturated solution of sulphate of copper may be advantageously applied by the brush. Cases occasionally occur in which the internal administration and also the local application of mercurials in conjunction with preparations of iodine are indicated. The more powerful applications and medicines may sometimes be beneficially alternated from time to time with the exhibition of chlorate of potash, both locally in the form of solution, spray, or powder, and internally in combination with tonics. Swollen and œdematous parts of the mucous membrane may be freely scarified with the greatest advantage; and any spot at which an abscess appears to have formed may be punctured. If any portion of exposed and necrosed cartilage should be seen, an attempt may be made to remove it by means of appropriate forceps.

In every case in which breathing becomes seriously impeded, whether in the secondary or tertiary stages of the malady, tracheotomy should be performed without hesitation. Ample experience proves that in syphilitic disease of the larynx this operation may be regarded as fairly successful, not only in averting impending danger, but also in affording opportunity for the more or less complete restoration of the parts affected.[1] The operation is especially called for in cases in which paroxysms of spasmodic dyspnœa have occurred, or in which laryngoscopic examination shows that the ulceration is extensive and deep, and some portion or other of necrotic or carious cartilage is exposed. In such cases recovery without operation, though by no means impossible,[2] is at any rate improbable; and the patient is in peril of his life (peril which at any moment may become imminent) until a new way of breathing is secured to him.

---

[1] See Türck, op. cit., p. 425.

The cicatrices of syphilitic ulcers of the larynx have a great disposition to contract, and such disposition is favored in many cases by the loss of substance which may have occurred. Permanent impairment of the voice, and more or less impediment to respiration may result. It not infrequently happens that tracheotomy becomes necessary after partial or complete cicatrization has taken place, in consequence either of the resulting contraction of the parts, or of an attack of laryngitis incidentally occurring. The damaged parts are prone to a low subacute or chronic form of inflammation, which at any moment may become exacerbated and give rise to urgent symptoms. In some cases the passage gradually becomes more and more free in consequence of the absorption of effused material; and in such, if it should have been necessary to perform tracheotomy, the canula may be removed at an earlier or later period. In other cases the contraction increases, and the tracheotomy canula must be worn during the remainder of life. In some few cases it may seem desirable to divide the cicatrices by operation, and to attempt the dilatation of the air passage. But so far as I have been able to ascertain, no very satisfactory result has hitherto been obtained in any case in which the mischief has been in the larynx itself. Much good however has been effected in several cases in which the contractions have been situated above the larynx. Some encouragement to further attempts may perhaps be derived from the successful results which have been obtained in instances in which the contractions have resulted from the effects of injuries, although, as is obvious, the conditions in such cases must necessarily be somewhat different.[1]

ERYSIPELATOUS LARYNGITIS.

Erysipelatous Laryngitis in its severer forms is an extremely dangerous, but happily by no means a common affection. It is most frequently met with, perhaps, in hospital practice at periods when erysipelas is prevalent. It may either occur in association with erysipelas of the face and neck by direct extension to the fauces, and thence to the larynx; or the fauces and larynx may be first affected, and death may ensue without any appearance of erysipelatous redness on the external surface.

The *local symptoms* are:—soreness of the throat; difficulty in swallowing; pain and tenderness about the larynx; hoarseness, and subsequently extinction of the voice; and difficulty in breathing, which may rapidly become more and more urgent. These local symptoms are preceded and attended by the constitutional symptoms (such as feverishness, rigors, etc.) associated with erysipelas generally. On *inspection*, the mucous membrane of the fauces is seen to be unnaturally red and swollen, and sometimes more or less dry and shining. By aid of the laryngoscope, the mucous membrane of the larynx may be seen to be similarly affected. As the malady advances the submucous tissue becomes infiltrated; the swelling increases, and its œdematous character is pronounced; the glottis becomes more and more encroached upon, and respiration is consequently more and more impeded.

Unless the malady is checked in its progress, or relief is afforded from the urgent symptoms, the patient usually sinks into a "typhoid" state, and dies either from exhaustion or suffocation. Such is the common result.

On *post-mortem examination* the mucous membrane of the larynx appears inflamed, swollen, and œdematous. In many instances it is of a dirty greenish color in places; and the submucous tissue is infiltrated with seropurulent matter, and here and there sloughy. Small collections of pus and sloughs of the areolar tissue are occasionally seen round the glottis. The tracheal mucous membrane is also often found to be inflamed. The mucous membrane of the fauces is similarly affected; and the base of the tongue and the tonsils sometimes present a more or less extensive sloughy appearance.

---

[1] I find that in 38 out of 72 cases of tracheotomy on account of syphilitic disease of the larynx which have come under my observation, or of which I have collected particulars, life was preserved. In 19 of these the patients were enabled sooner or later to dispense with the canula; in 10 it was necessary to wear the canula permanently; in 9 the ultimate results are not stated.

[2] See a remarkable case recorded by Gibb (op. cit., p. 38), in which a crater-like elevation was seen on one side of the glottis. From this, portions of the cricoid cartilage were discharged and expectorated on three different occasions.

[1] See the article on Injuries of the Neck. Vol. i., p. 694.

Treatment.—The general treatment must be from the first stimulating and supporting; and no effort must be spared to counteract the depressing influences of the disease. As much nourishing and easily digestible food as can be taken, together with a very liberal allowance of wine or brandy, should be given at frequent intervals in such proportions as can be swallowed. The tincture of the perchloride of iron with quinine should be administered in full doses, or some other powerful tonic combined with chlorate of potash, or ammonia.

In some cases it may be desirable to commence the treatment by the administration of an emetic followed by a purge. But the propriety of so doing must be decided by the general condition of the patient, and the progress the malady may have made. Locally, the application of a strong solution of nitrate of silver or perchloride of iron may be recommended in the earlier stages. In the more advanced stages, especially when there is much œdema, free scarification of the mucous membrane, and frequent inhalations of warm soothing vapors and steam may afford the most marked relief. If the dyspnœa becomes urgent tracheotomy must be performed. It is true that from the nature of the malady there is often but little hope of a successful result; at the same time there can be no doubt but that by the operation a chance of prolonging life is afforded that could not otherwise be obtained; and that by it at any rate the last hours of the patient may be rendered comparatively free from suffering.[1]

It may be worthy of remark that apart altogether from any such serious affection as that thus described, it not infrequently happens that in cases of erysipelas of the scalp and face, there is some soreness of the throat, slight difficulty of breathing, and some alteration of the voice, such as weakness or hoarseness.

DIFFUSE CELLULAR LARYNGITIS. ACUTE ŒDEMATOUS LARYNGITIS.

Diffuse inflammation of the areolar tissue of the larynx is a comparatively rare, but very formidable malady. It corresponds to the diffuse cellular inflammation not infrequently met with in other parts of the body; but it is especially dangerous on account of the impediment to respiration and swallowing to which from its situation it necessarily gives rise. It is probably closely allied in nature to erysipelatous inflammation, from which, however, it differs in the fact that in it the submucous tissue is primarily attacked, and the mucous surface is left free, or only becomes secondarily affected. In erysipelas, on the other hand, the mucous surface is first affected, and the submucous tissue is only secondarily or concomitantly involved.

Diffuse Cellular Laryngitis may either occur in association with previously existing diffuse cellular inflammation of the neck, in which case it seems to form a part of the more general affection; or it may commence in or about the submucous tissue of the pharynx and larynx, and thence spread through the neck generally. In some instances, however, it may cause death from suffocation or exhaustion before any considerable extension to other parts can have taken place.

In this malady the appearance of the local affection is usually preceded, and its onward progress is invariably attended, by more or less severe constitutional disturbance, and especially by great general depression. At the onset the patient often complains of having felt unwell for some days, and of having suffered from headache, lassitude, lowness of spirits, and other febrile symptoms. Soreness of the throat, at first slight, but rapidly becoming severe, is noticed early; and rigors soon occur. As the malady progresses breathing becomes impeded; and a sense of weight and oppression at the chest is complained of. There may be slight hacking cough, attended by the expectoration of a little whitish glairy mucus. The soreness of the throat increases; the fauces and tonsils become much swollen, and of a dusky red color; and sometimes ulcerated patches appear upon them. Somewhat later the glands behind and below the jaw become enlarged; the neck becomes painful; and the mouth can only be opened with difficulty. The throat is tender when external pressure is made on one side or both. Occasionally a constant and profuse discharge of saliva takes place. Still later, the neck becomes swollen, and the swelling extends and increases; respiration is more and more impeded; and swallowing is rendered almost or quite impossible. The patient sinks into a typhoid condition, and dies exhausted; or, as perhaps more frequently happens, he is killed by a process of slow asphyxiation. In some cases, however, a sudden paroxysm of spasmodic dyspnœa proves fatal at a comparatively early period in the progress of the malady; and in others, the laryngeal œdema increases very rapidly, and causes speedy suffocation. Either of such results may ensue before any considerable, or even any perceptible general swelling of the neck has taken place.

---

[1] A fatal result ensued in 10 out of 15 cases of tracheotomy performed on account of erysipelatous laryngitis which have come under my observation, or of which I have collected particulars; in 5 cases the patients made good recoveries.

So far as I have been able to ascertain, no satisfactory laryngoscopical examination has hitherto been made in any severe case of this kind; and therefore the actual appearances during life cannot be described. They may, however, be predicated with sufficient accuracy from what has been constantly observed on post-mortem inspection. Moreover, the swollen and œdematous condition of the upper part of the larynx may generally be easily ascertained by digital exploration. In the earlier stages and less severe forms of the malady, laryngoscopical examination to some extent is comparatively easy; and the mucous membrane of the upper parts of the larynx may be seen to be distended and swollen, and dusky or palish in color. The color of the mucous membrane differs altogether from the bright scarlet redness of acute catarrhal inflammation. The lower parts of the larynx are more or less completely concealed from view.

On *post-mortem examination* extensive inflammatory œdema of the submucous tissue of the larynx and neighboring parts is invariably found. In some cases one side is much more affected than the other. When cut into, the areolar tissues present an infiltrated, and sometimes more or less sloughy appearance. The infiltration is serous, seropurulent, or purulent in character, according to the period at which death has occurred, and the circumstances under which it has taken place. The tissues of the neck are found in many cases to be infiltrated to a greater or less extent with serous, seropurulent, or fibrinous exudation. In cases in which there has been much swelling, they often present almost a brawny consistency. Sometimes the infiltration extends upwards behind the pharynx, sometimes downwards alongside the trachea and œsophagus, even into the mediastina. Occasionally the infiltration in the neck is purulent in character, and in some instances the areolar tissue is sloughy and putrid.

Treatment.—The same general treatment is required as that recommended in erysipelatous laryngitis. But in this malady local applications of nitrate of silver, etc., are far less likely to prove efficacious. The swollen parts should be freely and deeply scarified at a comparatively early period; and the scarification should be repeated without hesitation from time to time according to circumstances. After the scarification, warm soothing vapors should be frequently, or almost constantly inhaled for a time. At a subsequent period the spray of astringent solutions may be inhaled with advantage. Further, in cases in which the neck is much swollen, it may be desirable to make careful but free incisions into it, not only to evacuate pus or to allow of the escape of serous effusion, but also with the view of diminishing the tension and consequent pressure upon the trachea and œsophagus.

If such means fail to afford relief, and the dyspnœa is urgent, tracheotomy must be performed, although the difficulties attending the operation may be great, and the chances of a successful result may appear small.

An excellent illustration of the value of tracheotomy in cases of this kind occurred some few years ago in the practice of Mr. Pollock at St. George's Hospital.

The patient (a butcher, aged forty-three) was admitted with severe and extensive diffuse cellular inflammation of the neck. Urgent laryngeal symptoms soon supervened. Tracheotomy was performed, and the patient made a good recovery in a comparatively short space of time.[1]

OTHER FORMS OF LARYNGITIS. EXANTHEMATOUS LARYNGITIS; TRAUMATIC LARYNGITIS, ETC.

Consecutive inflammation of the larynx occasionally occurs in the course of various general maladies, other than those the laryngeal complications of which have been already described in detail. It is especially liable to occur in measles and typhoid fever. It is more rarely met with in smallpox and typhus, and still more rarely in scarlet fever.

The *Laryngitis of Measles* is catarrhal in character, and, in most instances, appears soon after the nasal catarrh. Respiration may be more or less embarrassed; and sometimes there is remarkable harshness of the voice, and frequent harsh cough. In young children the breathing is occasionally stridulous, and the cough ringing. The consequences are very seldom serious; but it is well to bear in mind that they may possibly become so. In some rare instances, dangerous, and even fatal œdema of the larynx has ensued: and in some, the œdema has persisted after the general symptoms have subsided. In such cases the laryngeal symptoms have appeared early, and from the first have been very acute. As a general rule, the mucous membrane of the larynx is simply affected in a manner corresponding to the cutaneous eruption; and the symptoms subside as the eruption disappears. It is not often that any local treatment is necessary or desirable, beyond the application of warm poultices and fomentations to the neck, and the inhalation of warm soothing vapors. If, however, the symptoms are severe and persistent, the same treatment may be required as that recommended in cases of acute catarrhal laryngitis (see p. 49).

---

[1] See Lancet, September, 1863, p. 276.

The *Laryngitis of Typhoid Fever* is ulcerative and destructive in character.[1] It may either commence during the earlier or middle stages of the malady, concomitantly with the ulceration of the intestinal glands and mucous membrane, and speedily give rise to serious symptoms, or even to a fatal result; or its existence may first become manifest during the period of convalescence, and after all febrile symptoms have subsided. The ulcerations which occur during the earlier stages are generally situated either on the aryteno-epiglottidean folds, in the neighborhood of the arytenoid cartilages, or, according to Rokitansky, about the lateral walls of the larynx. They may give rise to more or less severe functional disturbance—often to cough, and difficulty of swallowing, and, somewhat less frequently, to difficulty of breathing. The difficulty of breathing usually corresponds to the amount of inflammatory œdema that may have occurred. It is sometimes difficult to determine how far the cough may depend upon laryngeal, and how far upon bronchial affection. It is probable that in a large proportion of cases, if the patient survive the general malady, these ulcerations heal favorably, like the corresponding intestinal ulcerations. But in cases in which the symptoms become manifest at a comparatively late period in the course of the malady, or in which ulceration goes on insidiously, and perhaps almost unnoticed until seeming convalescence has taken place, the perichondrium and cartilages (and especially the cricoid) are very liable to be implicated to a greater or less extent. Under such circumstances the consequences are often very serious. Necrosis of the cartilages may result in association with typhoid fever, not only from gradual penetration of the ulcerative process, but also in some cases as an effect of some deep-seated inflammatory condition commencing in or about the cartilages themselves.

A remarkable instance came under my observation in Guy's Hospital, while I was acting as Ward Clerk to the late Dr. Addison. A boy, ten years of age, had apparently recovered from typhoid fever. One morning he complained of pain in the throat. A day or two afterwards he expectorated some pus. The next day his neck was observed to be swollen and emphysematous. The emphysema rapidly spread over the whole body, even to the scrotum and penis, which became enormously and peculiarly distended. Two days later death occurred. On post-mortem examination a small ulcerated opening, leading down to a necrosed portion of the cricoid cartilage, was found below the glottis, on the right side. Through this opening evidently the air had escaped during expiration into the areolar tissue of the neck, and had thence spread over the body. No other case of any kind has ever come under my observation in which the emphysema was so extensive and so general. The cavities as well as the superficial parts of the body were affected; and indeed it appeared probable that death had resulted from the impediment to respiration caused by the intrathoracic emphysema.

In a certain proportion of cases in which the symptoms are not severe, recovery may take place without any local treatment beyond the application of warm fomentations to the neck, and the inhalation of warm soothing vapors. The general treatment of typhoid fever must, of course, be carried out. In all cases, however, in which the symptoms are urgent, tracheotomy should be performed. It is undeniable that the statistical results hitherto obtained, do not appear to be very encouraging.[1] At the same time the success which has resulted in some cases justifies resort to this operation, which indeed alone offers any chance of safety.

In the *Laryngitis of Smallpox* the mucous membrane is affected in a manner which varies with the stage of the malady, and corresponds more or less closely with the more obvious external appearances. In the earlier stages, pustules may arise analogous to those observed on the cutaneous surface. Neumann, Türck, and Krishaber, all state that they have seen, by aid of the laryngoscope, true variolous pustules, surrounded by circumscribed inflammatory areolæ, upon the true vocal cords, as well as on other parts of the laryngeal mucous membrane. The symptoms are, hoarseness, cough, and more or less uncomfortableness or pain about the larynx. About the eleventh or twelfth day, at the period at which swelling of the face and extremities is especially liable to occur, œdema of the larynx may come on; and respiration may be more or less seriously, or even fatally impeded. During the still more advanced stages of the malady, at or about the period at which abscesses are occasionally formed in other parts, perichondritis and subsequent necrosis of cartilage, with all the attendant symptoms and dangers, may ensue.

---

[1] This affection is the *laryngo-typhus* of the Germans. It appears to have been first definitely and fully described by Louis, in whose treatise, entitled Recherches sur la Fièvre typhoide (Paris, 1841), much valuable information on the subject is contained. Trousseau especially refers to the laryngeal complications of typhoid fever, and gives some excellent illustrative cases in his Clinique médicale, vol. i., p. 299; Paris, 1868. Chomel, Rokitansky, Wilks (Med. Times and Gaz., 1862, p. 276), and others also fully discuss the pathological history, or give examples of typhoid disease of the larynx. The appearance of the ulcers is so characteristic that Louis says that, if observed in a patient who had died of some acute disease, they would be sufficient to indicate almost certainly that the affection had been typhoid fever. Op. cit., p. 321.

[1] I find that out of thirty-five recorded cases in which tracheotomy was performed on account of "typhoid" disease of the larynx, in twenty-four death ensued. In eleven life was saved; but in several of them the voice was permanently impaired, and the canula could never be dispensed with.

In *Scarlet Fever* the larynx may either be affected during the earlier stages by extension of inflammation or inflammatory œdema from the pharynx; or, in common with other parts, it may become œdematous as the result of consecutive kidney disease. The true scarlet-fever eruption very rarely indeed, if ever, invades the larynx. The local treatment necessary in each case may be gathered from what has been already stated in regard to similar affections arising in connection with other maladies.

It may here be remarked that in *Bright's disease* the larynx may participate in the general œdema, and this may prove dangerous or fatal from the obstruction to respiration to which it gives rise.

Gouty laryngitis may possibly be considered to possess small claim to be described as a distinct form of disease. But it is worthy of remark that in gouty subjects chronic laryngeal affections are by no means uncommon. Sometimes they are very troublesome, and even distressing to the patient; and they are always difficult to treat successfully unless the existence of the general condition upon which they depend is fully recognized, and modified by appropriate constitutional remedies. In many cases they occur in association with gouty bronchitis and tracheitis, but even in some of these the laryngeal symptoms may attract most attention, and give rise to most trouble and danger. In certain rare instances acute laryngitis of very formidable character has been observed to occur in connection with an attack of gout.

Traumatic laryngitis has been already described in the chapters treating on the various injuries—as wounds, blows, burns, etc.—from which it may result (see Article on INJURIES OF THE NECK, Vol. I.).

NEW GROWTHS. POLYPI, ETC.

New growths in the larynx were formerly supposed to be of very rare occurrence; and indeed, except in some few and very remarkable instances, their presence could only be determined on post-mortem examination. Since the laryngoscope has come into use, however, a large number of cases have been recorded; and many more at present unpublished have come under observation, in which growths in the larynx have not only been recognized during life, but have been successfully removed by operation. There is probably no other class of cases in which the value of the laryngoscope has been so signally demonstrated. It would appear not unlikely that this circumstance, together with the interest naturally attaching to cases of this kind and the attention consequently attracted to them, has been the means of leading to the now prevalent idea that they are even more common than is actually the fact. They are certainly more frequent than was formerly supposed; but they nevertheless constitute only a very small proportion of the affections of the larynx that come under every day observation. Krishaber states that such growths are to be "met with in two or three per cent. of the cases of maladies of the larynx exclusively local and chronic."[1] My own experience would lead me to the conclusion that they are much less frequent even than this.

The new growths in the larynx met with in different cases vary in character, size, and precise situation, and also to a corresponding extent, in the symptoms to which they give rise and in the degree of danger they immediately involve. They may occur at any period of life; in some instances they are congenital;[2] in others they do not appear until advanced age. They are almost equally common in the two sexes. No satisfactory conclusion has yet been arrived at as to the local or general determining causes of their appearance in the majority of cases. In some instances, however, they may be of syphilitic origin; in others the so called new growths may be simply the thickened elevations of surface, or the "vegetation-like" granulations of phthisical laryngitis.

---

[1] Op. cit., p. 730.

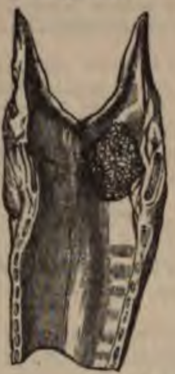
[2] One case has come under my own observation in which it was evident that the growth had commenced before, or immediately after birth. Another case, also congenital, is recorded by Mackenzie (Path. Trans., 1865, p. 38). Three are recorded by Gibb (op. cit.) and several are quoted by Causit in his Étude sur les Polypes du Larynx chez les Enfants Paris, 1867.

Some approximative idea as to the relative frequency of the different kinds of new growth met with in the larynx may be obtained from the following table, which has been carefully compiled from the published records of cases, from the results of my own observations, and from the descriptive catalogues of various museums.

Nature of growth.	Number of cases.	Number in which the growths were recognized during life.	Number in which they were only found after death.
Papillomatous or warty	110	65	45
Fibrous	23	13	10
Fibrocellular. Sarcomatous, etc.	52	47	5
Glandular. Adenomatous	6	2	4
Cystic	14	9	5
Cartilaginous	4	...	4
Epitheliomatous. Cancerous	19	8	11
Not clearly indicated	16	14	2
Total	244	158	86

Papillomatous or Warty Growths, as will be seen by the above table, constitute a large proportion of the new growths met with in the larynx. In structure and appearance they bear a general resemblance to growths of similar nature found in other parts; they may occur either as little warty elevations, consisting of comparatively few, and sometimes almost acuminated papillæ, or as closely packed and multitudinous villous or filipendulous outgrowths, or as densely massed "cauliflower-like" agglomerations of elongated and enlarged papillæ, rounded or flattened at their extremities. They most frequently, perhaps, spring from the mucous membrane of the anterior part of the larynx, somewhere near the insertion of the true vocal cords. In many instances, they take origin from the boundaries of the ventricles, and in some from the true vocal cords; but they may arise from almost any part of the laryngeal mucous membrane. As a rule, they are multiple in origin, and spring up simultaneously or successively in several different places. Sooner or later, they more or less completely coalesce so as to form one or many distinct masses. Some idea of the general appearance presented by growths of this kind, may be conveyed by Fig. 560, which is taken from a preparation in the Museum of Guy's Hospital.[1] The growths in this case form a single mass, which cannot be considered as otherwise than of moderate dimensions when compared with those met with in many other instances. It was sufficiently large, however, to lead to a fatal result. In some cases these growths increase very rapidly, and to such an extent as to fill altogether, and sometimes even to distend the cavity of the larynx.

Fig. 560.



Papilloma of larynx springing from border of left ventricle. Larynx opened in front.

A very remarkable instance is recorded and figured by Bruns.[1] In another case of the same kind, of four or five years' standing, in which I removed the growths after having laid open the larynx, it appeared remarkable that such a mass as was removed could ever have found room in so small a space.[2] The laryngeal mucous membrane was literally covered by growths, which varied in size and density. The patient nevertheless made a rapid recovery, and has now a very fair voice.

---

[1] Preparation No. 1703.

[1] Op. cit., Beobachtung viii.

[2] Tracheotomy had been performed about four years previously.

In most cases the rapid increase of the growths, or the general inflammatory condition which may arise in association with their presence, and the consequent obstruction to respiration, render tracheotomy necessary, or without this operation, lead to a fatal result at a comparatively early period. But in some instances patients suffering from laryngeal growths of this kind have been known to live for years. In such cases, it is probable that the larynx has been kept sufficiently clear for breathing purposes by the detachment and expectoration of portions of the growth from time to time during coughing. Türck records a case in which the whole growth appears to have been thus got rid of.[1]

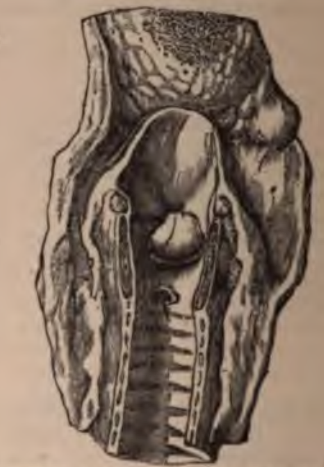
I have at the present time a little girl under my care in Guy's Hospital, whose trachea I opened three years ago on account of a growth of this kind, and with the view of subsequently removing the growth. The parents, however, objected to any further operation. The child's voice has improved, and the growth is now visibly smaller than it was two years ago when I previously examined her laryngoscopically. She cannot, however, dispense with the tracheotomy canula, although she is able to some slight extent to breathe through the natural passage.

According to some observers, it would appear that these papillomatous growths occasionally undergo a process of pulpy or caseous degeneration.[2] In such case it is easy to understand that they may become broken down and expectorated.

Fibrous and Fibrocellular Growths are met with in the larynx much less frequently than the papillary growths above described, but numerous instances are on record.

These growths are smooth on the surface, hemispherical, globular, or pyriform in shape, and on laryngoscopical inspection they appear somewhat paler in color than the mucous membrane of the surrounding parts. In substance they are more or less firm and compact. In structure, they resemble growths of similar nature developed in other parts; as a rule, they are solitary; they may be sessile with broad base, or pedunculated. If pedunculated, the pedicle is generally less firm and more vascular than the growth itself. In a large proportion of cases these growths are comparatively small, and do not each exceed the size of a pea; but they may attain considerable dimensions. In an instance referred to by Rokitansky, the growth was as large as a pigeon's egg.[1] A pedunculated fibrous growth of medium size is represented in Fig. 561, which is taken from a specimen in the Museum of Guy's Hospital.[2]

Fig. 561.



Pedunculated fibrous polypus of the larynx arising near the anterior extremity of the right ventricle of the larynx.

The larger pedunculated growths generally take origin from one or other of the true vocal cords, or from some immediately adjoining part of the ventricular wall—and in the latter case most frequently near the anterior extremity of the ventricle. They may, however, arise in other parts of the larynx, but they very seldom do so; in scarcely any instance has a growth of this kind been found connected with the mucous membrane covering the arytenoid cartilages.

Adenomatous or Glandular Growths are occasionally but rarely met with in the larynx. As a rule, they take origin from the mucous membrane covering the arytenoid cartilages, the aryteno-epiglottidean folds, or the base of the epiglottis,—or in general terms from those parts o the mucous membrane which are naturally most abundantly supplied wit glandular structures. In this respec they differ remarkably from all othe laryngeal growths of non-malignant cha racter. They consist essentially of enlarged and hypertrophied glands and follicles, surrounded by more or less thickened submucous connective tissue and mucous membrane. Occasionally they appear to contain adenoid structures of new formation. They may be sessile or pedunculated. When sessile (localized glandular hypertrophy of the mucous membrane), they often present a more or less lobulated appearance; and in some instances they attain very considerable dimensions.[1] When pedunculated they are usually more or less pyriform or globular, and their peduncles are proportionately longer than those of the fibrous polypi. When seen during life, by aid of the laryngoscope, these growths are generally of a deepish red color, but they often become pale as they advance in age. They are remarkable for the rapid changes in volume they are liable to undergo under various circumstances. Thus a slight attack of catarrhal laryngitis is almost sure to be attended by speedy and considerable increase in the size of the growth, which, may, however, again become smaller as the inflammatory condition passes off.

[1] Zeitschr. d. k.k. Gesellsch. d. Aerzte Wien, 1851, quoted by Krishaber. Op. cit p. 730.

[2] Preparation No. 1703^{20}. Tracheotomy ha been performed in this case; and the patie had for a long time been comparatively co fortable, but voiceless. One day the tube g displaced. Spasm of the larynx, conjoin with the mechanical obstruction caused the growth, proved immediately fatal.

Cystic Tumors of various kinds are met with from time to time in the larynx; but instances are comparatively rare. In some cases they may possibly result from the degeneration and breaking down of myxomatous growths, as suggested by Cornil and Ranvier;[2] but more frequently, probably, they owe their origin to causes corresponding to those which lead to the development of similar cysts in other parts. In some cases their contents are serous, or serosanguinolent; in others mucous, albuminous, or synovial in character. They may occur in almost any part of the larynx, and in some cases have attained considerable size.[3]

An interesting, and I believe almost unique example of mucous cyst connected with the posterior aspect of the epiglottis, came under the care of Dr. Wilks and myself in Guy's Hospital some few years ago. The patient, a delicate boy eleven years of age, had suffered two years previously from a severe attack of sore throat, and ever since had experienced more or less difficulty in swallowing. This difficulty gradually increased. His voice soon became affected, and by-and-by he began to suffer from frequent and severe attacks of dyspnœa, which often came on during sleep. On laryngoscopic examination, the epiglottis was not to be seen presenting its ordinary form; but instead of it there appeared a large rounded swelling, projecting downwards and backwards, and completely covering in and concealing the glottis. The tumor was pale in color, shining, and somewhat translucent in appearance. It could be just reached by the finger, and was elastic, but very tense to the touch. Feeling certain that it contained fluid, I made a free incision into it, by means of a curved, sharp-pointed bistoury. A sudden gush of thick, glairy, muco-purulent matter took place; and after the momentary dyspnœa which occurred had subsided, the patient was relieved of all the symptoms from which he had before suffered so severely. He made a rapid recovery, and left the hospital quite well. I examined him laryngoscopically four years afterwards (as well as from time to time in the interim), and could discover no indications of any return of the disease, nor indeed any very clearly perceptible mark of my incision.[1] A case of somewhat similar kind is recorded by Delorme, in which two cysts, with glairy albuminous contents, were found on the posterior aspect of the epiglottis of a man forty years of age, who died asphyxiated.[2]

It is worthy of remark, perhaps, that *true hydatid cysts* are stated to have been found in the larynx in some few very exceptional cases.[3]

A few instances of *Cartilaginous and Osseous Growths* in the larynx are on record; but the accounts given, so far as I have been able to make out, are not altogether satisfactory.[4]

Besides the growths of the various kinds thus described, others of mixed form and character are occasionally met with in the larynx. Thus the fibrous, fibro-cellular, and glandular elements may vary in relative proportion in such manner and to such extent as may render it impossible to assign the particular growth under examination to any definite class. And so again some growths which superficially appear papillomatous may have firm fibrous bases. And, further, the condylomata of syphilis, the thickened elevations of phthisis, and the small protuberances resulting from localized chronic inflammation in some cases can hardly be distinguished from what more properly, perhaps, ought to be regarded as "new growths" in the strictest acceptation of the term.

---

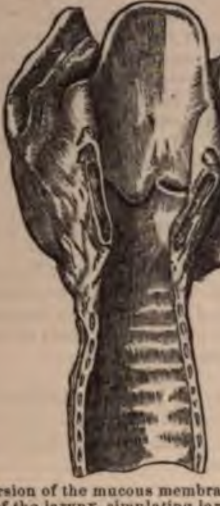
A very interesting specimen was almost accidentally met with some short time since in the post-mortem room at Guy's Hospital, in which there was extroversion of the mucous membrane of the left ventricle of the larynx. Fig. 562 conveys a somewhat feeble idea of the appearance presented. The extroverted mucous membrane could be easily replaced in its proper position; and when this was done there was nothing abnormal in the appearance of the larynx. The patient had had no laryngeal symptoms.[1]

Fig. 562.



Extroversion of the mucous membrane of the left ventricle of the larynx, simulating laryngeal polypus.

Cancerous Growths in the larynx are, for the most part, *epitheliomatous* in character; but instances of *medullary cancer affecting the larynx* are not wanting.

Epithelioma of the larynx generally commences on the pharyngeal aspect of the mucous membrane covering the arytenoid or cricoid cartilages, and subsequently invades the interior of the larynx. But in some instances it commences inside the larynx; and in such cases, as a rule, it first appears on the mucous membrane of the posterior and lower part, over or near the internal surface of the cricoid cartilage, in the form of small irregular nodules, which gradually increase in size and soon ulcerate. Three instances of epithelioma commencing in this situation, and in the manner described, have come under my own observation. In each the precise position and character of the growth were recognized at a comparatively early period; and in each the result of the case established the correctness of the diagnosis. The distinctive features of advanced epithelioma of the larynx, as seen by the aid of the laryngoscope, have been already described (see p. 60).

The *symptoms* to which "new growths" or "polypi" in the larynx give rise vary in character and severity with the dimensions and precise relations of the particular growths under observation; and also with the intensity of the inflammatory condition which in many cases may be excited by their presence, or at any rate may be sooner or later associated with it.

Difficulty of breathing, alteration or extinction of the voice, cough, and, it may be (especially in the case of cancerous growths) difficulty of swallowing; these are the symptoms—as indeed they are also the symptoms, varying only in intensity and urgency—in all serious affections of the larynx, as well as in some other maladies in which the larynx is only indirectly affected. It is very rarely indeed, if ever, that any one of these symptoms manifests such peculiarities as may be considered to indicate the presence of a "new growth."

In many cases when the patient first comes under observation the difficulty of breathing is so urgent, or becomes urgent so speedily, that tracheotomy must be performed before any exact diagnosis can be made. The difficulty of breathing may depend either upon the mechanical obstruction caused by the growth, or upon spasm of the larynx excited by an incidental contact of the growth with some unaccustomed, or already irritated part of the highly sensitive boundaries of the glottis. A growth may exist for a long time almost harmlessly, moving in correspondence with the respiratory movements of the larynx, and then all at once may get into such position as to excite the most severe attack of spasmodic dyspnœa. This is especially likely to occur in the case of pedunculated growths. It may occur in other cases, if from any cause an attack of ordinary laryngitis should supervene. Sessile growths by their gradual increase may gradually constrict th aperture of the glottis, and thus proportionately impede respiration, withou giving rise, at least during their earlie stages, to any such suddenly serious an dangerous results as those thus indicated

In the case of growths situated belo the glottis it may happen that expiratio is almost as much impeded as inspiratio

In some cases by means of the steth

---

[1] The case is fully described by Dr. Moxon, Trans. Path. Soc., 1868, p. 65. The preparation is in the Museum of Guy's Hospital. Preparation 1683.

scope placed over the larynx a sound produced by the movements of the growth during respiration (the "bruit de drapeau" of the French) may be detected.

The voice is affected to a greater or less extent in almost all cases; and if the growths are small and situated on the vocal cords, the affection of the voice may be the only symptom of which the patient complains. The voice may be simply changed in tone and quality, and become harsh; or it may have the "cracked pot" or "Punch" sound; or it may be reduced to a hoarse whisper; or it may be altogether extinguished. In some exceptional cases the voice, at first seriously affected, has been noticed to improve to a certain extent with the increase of the growth.

In a considerable proportion of cases there is little or no troublesome cough. But if an attack of catarrhal inflammation should occur, the cough becomes especially distressing; and fits of spasmodic cough may be excited from time to time in any case in which a pendulous tumor is liable to get into obstructive position. Occasionally the patient becomes conscious of the presence of some cause of obstruction, and tries "to cough it up."

Slight mucous or mucopurulent expectoration may attend the cough; sometimes portions of the growths may be mingled with the expectorated material;[1] and, as already stated, in some exceptional instances considerable portions, and even the whole of the "new growths" have been got rid of in this manner.

Among the various affections which may give rise to symptoms similar to those thus referred to as caused by the presence of new growths in the larnyx, may be enumerated—chronic laryngitis with œdema; spasm of the larynx, from whatever cause; laryngismus stridulus; nervous aphonia; pressure upon the pneumogastrics or the recurrent branches by tumors, aneurisms, etc.; retropharyngeal abscesses; pharyngeal polypi hanging down or projecting into the larynx, etc. It is, however, in the present day altogether needless to discuss in detail the distinctive differences that may or may not be presented by the symptoms in these several affections. In all cases in which time and opportunity are at command the diagnosis may be readily determined by aid of the laryngoscope. In cases however, in which the symptoms are very urgent, whatever may be their cause, relief must be afforded and safety secured by tracheotomy or otherwise before any full inquiry can be entered upon: laryngoscopic examination may then be made under favorable circumstances at any convenient subsequent period. It occasionally happens in the case of growths taking origin low down, that they almost disappear under the vocal cords or into the ventricles during inspiration, and only come thoroughly into view during expiration.

It is worthy of note that in some cases, particularly in children who are difficult subjects for laryngoscopical examination, valuable, if not conclusive indications may often be obtained by digital exploration. The effort at vomiting commonly excited during the introduction of the finger into the pharynx causes the larynx to rise momentarily, and thus to come within easy reach.

Treatment.—Measures should be adopted for the removal or destruction of all nonmalignant new growths in the larynx as soon as practicable after their presence and probable character have been clearly ascertained. For it may be asserted without fear of contradiction that no patient can be considered safe who has in his larynx a new growth of any considerable size—that is to say, unless his safety has been secured by tracheotomy. And small growths, as already stated, are liable to enlarge more or less quickly, and often unexpectedly; and even while still small they may favor the supervention of dangerous inflammation.

In some cases it is absolutely necessary, and in others it may be desirable, to perform tracheotomy before proceeding to any further operative measures. Very many cases, however, have now occurred in which, without tracheotomy, growths have been removed from the larynx, not only with the best ultimate results, but also without having involved the patient even temporarily in any serious risk.

The advisability of performing tracheotomy as a preliminary measure must be determined by the urgency of the symptoms, and the probable difficulties and dangers of the proceedings about to be carried out.

A great variety of different methods have been devised and adopted for the removal of growths from the larynx. They may be divided into those in which the operation is performed by aid of the laryngoscope through the mouth and natural passages, and those in which access is first obtained to the interior of the larynx by means of incisions in the median line through the skin, cartilages, etc.

---

[1] It may be interesting from an historical point of view, to quote the words of Ehrmann, writing in the year 1850: "Il n'existe, il faut le dire, qu'un *seul* signe certain de l'existence de cette maladie; c'est l'expuition de quelques parcelles du polype."—Op. cit., p. 31.

Table of Cases of Operations for the Removal of New Growths from the Larynx.[1]

Methods adopted.	Total number of cases.	Completely successful results.	Partially successful results.	Deaths.
A. OPERATIONS THROUGH THE MOUTH AND NATURAL PASSAGES:				
Direct application of caustics or powerful astringents	16	12	4	
Removal or crushing by forceps . .	37	33	3	1
Removal or crushing by wire snare .	32	28	3	1
Removal or destruction by the galvano-caustic wire or pencil . . .	5	3	2	
Removal by knife or scissors . .	20	14	5	1
Simple puncture	4	4		
B. OPERATIONS AFTER EXTERNAL INCISION INTO THE LARYNX, ITS CAVITY BEING MORE OR LESS COMPLETELY LAID OPEN	24	15	5	4
Total	138	109	22	7

The above table, compiled from published records of cases and the results of my own observations, may serve to convey some idea as to the relative frequency with which the different methods of operating specified have been deemed expedient, as well as the degree of general success that has attended the efforts hitherto made.

The table must be taken for what it may be worth. It certainly appears to indicate the methods of operating that have hitherto been found most successful. But it cannot for one moment be regarded as affording any trustworthy guide to the method that ought to be adopted in any particular instance that may come under observation.

In deciding upon the course to be pursued, it is necessary in every case to take into consideration not only the size, precise situation, and character of the growth, but also the age, development, and condition of the patient, together with his general and special powers of endurance. If success is not attained by the method first adopted, another may be tried. Several methods were put in practice in each of many of the cases included in the above table. But in every instance the case is referred to the method which finally proved successful.

A. Operations through the Natural Passages.

1. *The Application of Caustics and powerful Astringents* to growths in the larynx, may be accomplished by the several methods already described (see p. 44); in the case of small isolated papillary growths, such applications, several times repeated, are not unlikely to prove efficacious.

2. Small fibrous, fibroid, and fibrocellular growths, and small or large papillary growths may, in many cases, be successfully seized by means of properly-adapted *Forceps*, and either torn off and removed in mass, or so crushed as to lead to their destruction. In the case of multiple growths, the repeated use of the forceps is often necessary. Portion after portion may be removed either at the same sitting, or during a series of sittings at intervals, according to circumstances. This method is especially advocated by Mackenzie,[1] and the laryngeal forceps which bear his name (fig. 563), are, I believe, the most generally applicable, and therefore the best of all the instruments yet devised for such purposes. Forceps made upon the principle illustrated in Fig. 564 are also very efficient. Some of these forceps are made to open laterally, and others antero-posteriorly, like those represented in the figure. In some cases ordinary laryngeal forceps, such as those figured and described in the chapter on Foreign Bodies in the Larynx (see Vol. I., p. 712) have been used with perfect success.

3. For the removal of laryngeal growths by *the Wire Snare* it is necessary to employ a slender and appropriately curved instrument carrying a wire loop, which can be quickly and easily drawn home when once it has been made to encircle the growth. The instrument successfully used by Dr. Walker, of Peterborough, in the first case in which a laryngeal growth

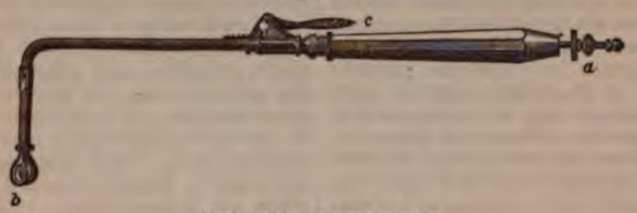
---

[1] In the cases specified as "completely successful" the voice was restored. In those "partially successful" the voice remained more or less impaired. In the fatal cases, with two exceptions, the growths were epitheliomatous or cancerous in character.

[1] Op. cit., p. 114.

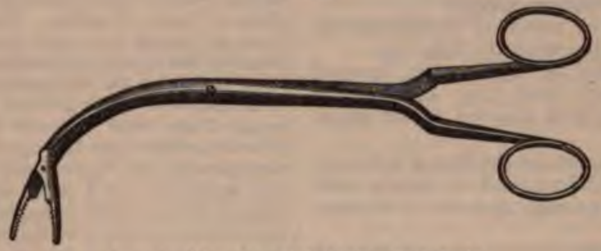
was removed from the larynx during life in this country, was a modification of Gooch's double canula.[1] But the double tube is cumbersome and altogether unnecessary. Gibb's Laryngeal Écraseur[1] is a far more perfect instrument—indeed, nothing could be better adapted for its purpose, unless it be some such modification as that suggested by Dr. George Johnson.[2] These instruments bear a general resemblance in construction and mode of working to Wilde's Aural Polypus Snare, and Hilton's Nasal Polypus Snare (see Vol. II., p. 250, fig. 300); but they are, of course, different in shape and more slender. In using this instrument the wire loop is made to encircle the growth, and then pulled tightly home. The growth is then forcibly pulled or twisted from its attachment, and, as a rule, is brought away in the loop. This method is strongly advocated by Sir G. D. Gibb,[2] and Dr. George Johnson.[3] It is especially applicable in cases in which the growths project in such manner and direction as to render them easily caught, and in which they are soft or pliable in texture, and not very large.

Fig 563.



Mackenzie's laryngeal forceps.

Fig. 564.



Laryngeal forceps, opening antero-posteriorly.

4. *The Galvanocaustic Method* was first practised by Middeldorpf, and has since been adopted by Voltolini, Türck, Bruns, and others. It has been still more recently recommended by Dr. Reichel, of Breslau.[4] This method consists in encircling and cutting off the growth by means of a platinum wire, which is so arranged in an appropriate carrier that when in position it can be intensely heated by means of a galvanic battery with which it is connected. The difficulties of this method are sufficiently obvious, and they, together with certain other practical objections to it, are clearly and forcibly stated by Bruns,[3] after some experience of its use. Its advantages in certain cases are equally obvious; and it would appear to be especially applicable in cases in which single fibrous growths exist, the peduncles of which are too strong to permit them to be safely torn away by means of the snare or forceps. A touch of the heated wire may be sufficient to dispose of small papillomatous growths.

5. *The Knife*, properly curved and guarded, or the *Laryngeal Scissors*, may be used for the separation of firmly attached growths which may have been seized but cannot be pulled off by the snare or forceps. Such means were adopted in several of the cases successfully treated by Bruns.[4] Several different

[4] See Table, op. cit., p. 254.

forms of laryngeal guillotine have been devised. Of these Mathieu's is probably the best. It has been used with success in several cases.

6. *Simple puncture* by the guarded bistoury or some specially contrived instrument (such as Mackenzie's laryngeal lancet) has proved completely efficacious in several instances in which the growths were cystic in character; and in such cases this method may be recommended. If in any case the cyst should fill again, it may be desirable on a second occasion to remove a portion of the cyst wall, or at least to make a more extensive incision than the previous one.

[7. *Transfixion of the growth* by means of a needle-knife passed through the cricothyroid membrane, or between the wings of the thyroid cartilage, and excision under guidance of the laryngoscopic mirror —a mixed operation, partaking of the nature of subcutaneous surgery.

8. *Excision* by means of sharp-eyed catheters made to sweep the interior.

9. *Detachment by dry sponges*, brushed rather roughly over the site of the growth; a method adapted to soft structures only.

10. Detachment by the finger-nail; applicable to children, and to adults with growths high enough up to be within easy reach.]

It is scarcely needful to add that all these several methods of removing laryngeal growths [save 9 and 10] require during their execution the guidance afforded by the laryngoscope.

B. Operations for the Removal of Laryngeal Growths after Exposure of the Cavity by External Incision and Section of the Cartilages, etc.[1]

In cases in which the growths are numerous, or very large, or single but firmly attached, and in those cases again in which the patients are young, and ill able to bear the introduction of instruments through their narrow natural passages, there can be no doubt, I think, that the easiest, most certain, and at the same time the safest method of operating consists in laying open the cavity of the larynx by external incision, and then removing the growths by scissors, écraseur, or galvanocaustic wire. The results of experience[1] encourage the further and more confident adoption of this procedure in all such cases as those referred to. It affords opportunity for the more immediate, complete, and effectual removal of the growths than can be obtained in any other manner. It is by no means difficult of execution, nor does it involve any immediate risk. Such bleeding as may occur can be readily checked, for all the parts are fully exposed; and freedom of respiration may be secured by the preliminary performance of tracheotomy; if, indeed, this operation have not previously been rendered necessary.

A good illustration of the success attending this method is afforded by the case of a girl, thirteen years of age, under my care some years since in Guy's Hospital. Tracheotomy had been performed four years previously on account of the urgent dyspnœa from which she then suffered. On laryngoscopical examination, masses of warty growths were distinctly seen. These were removed by the scissors after exposure of the laryngeal cavity by section through the thyroid cartilage, cricothyroid membrane, and other structures. Nitrate of silver was freely applied to the bleeding surfaces. The growths had occupied the whole cavity of the larynx. The divided parts were brought together. The patient made a speedy recovery, and the tracheotomy canula, which she had worn for four years, was removed ten days after the operation. I saw her the other day, three or four years after the operation. She was in good voice, and no appearance could be discovered of any recurrence of the growths.[2] In two other cases in which I have performed similar operations, the results have been so far equally satisfactory.

A remarkable case is recorded by Balassa, of Pesth. The patient, a young woman, twenty-one years of age, had suffered from more or less difficulty of breathing, and had been aphonic for more than two years. On laryngoscopical examination growths in the larynx were seen. Balassa laid open the larynx by section through the thyroid cartilage, and removed five portions of new growth. The patient made a good recovery, and her voice returned. Less than a year afterwards, she again lost her voice, and experienced increased difficulty in breathing. Balassa a second time opened her larynx through the thyroid cartilage in the situation of the old cicatrix. Three or four portions of new growth were removed. The patient

---

[1] It is worthy of note, that the first recorded operation of this kind was performed in the year 1844, by Ehrmann, who, without the aid of the laryngoscope (not then in use), diagnosed the existence of growths in the larynx from the symptoms and the appearance of portions in the sputa. He was justly so confident of the correctness of his diagnosis, that he boldly opened the larynx by median section, found the growths, removed them, and cured his patient. Laryngotomie dans un cas de Polype du Larynx; Strasbourg, 1844. Also, op. cit.

[1] See especially the excellent treatise of Dr. Charles Planchon, Faits cliniques de Laryngotomie; Paris, 1869. In this treatise a large number of illustrative cases are given.

[2] See Guy's Hospital Reports, 3d series, vol. xii., p. 541.

again made a good recovery; and as the result, was altogether relieved of her dyspnœa, and regained her voice.[1]

In operations of this kind the thyroid cartilage and crico-thyroid membrane may be divided in the middle line probably with impunity. But it is desirable to avoid, if possible, cutting through or otherwise damaging the cricoid cartilage.

MM. Pratt and Follin have each succeeded in removing tumors from the larynx after having divided the thyrohyoid membrane and superficial structures by transverse incision.[2] The objections to this method, arising principally from the necessary section of the hyoidean muscles, as well as from the imperfect extent to which the cavity of the larynx is exposed, are sufficiently obvious.

[In certain cases direct access may be had to the neoplasm through an incision practised through the crico-thyroid membrane only.]

In the case of epitheliomatous and other cancerous growths, it would appear to be worse than useless to attempt removal, without first fully opening the larynx and exposing the whole extent of the morbid structures. Whether any such attempt is justifiable the circumstances of the case must decide. As a general rule tracheotomy becomes necessary sooner or later; and it is probable that when once the character of the malady is recognized the earlier the operation is performed the better.

[Extirpation of the entire larynx, or of a portion only, alone or in connection with other structures, has been practised successfully in cases of malignant growths, hopelessly involving the larynx. The majority of patients thus treated have died shortly after the operation; and it is doubtful whether, on the whole, any prolongation of life secured in exceptional cases, justifies the absolute sacrifice of existence entailed as the rule.]

NERVO-MUSCULAR AFFECTIONS OF THE LARYNX. NERVOUS OR FUNCTIONAL APHONIA. HYSTERICAL APHONIA. PHONIC PARALYSIS, ETC.

Nervous, or functional aphonia.—Numerous cases come under observation from time to time in which the voice is lost, and in which also, more or less difficulty in breathing may occasionally occur, although no visible defect or disease can be discovered in the larynx itself on the most careful and complete laryngoscopical inspection. It may be seen that the several parts do not act properly, and that is all. Why they do not so act cannot be satisfactorily made out. Sometimes when the patient tries to utter a sound the glottis may be seen to remain widely open, and no sound is produced. Sometimes one of the vocal cords appears to come into proper position, the other remaining motionless, and apparently paralyzed. Sometimes the vocal cords seem to approximate naturally at the commencement of the attempt to speak, and then separate without vibrating, as the air from the lungs is forced against them. Other odd phenomena may be observed by the aid of the laryngoscope.

Alluding to cases of this kind, Sir Benjamin Brodie states[1] (and his statements are supported by general experience and observation):—

> "This affection takes place suddenly, continues often for many months, even for one or two years, and then disappears as suddenly as it began. A patient thus affected may, when under the influence of strong mental emotion, find herself speaking in her natural voice, when for some time before she had spoken only in a whisper. Her recovery may be permanent, or she may relapse into her former condition. And again, this affection is not unfrequently met with in the male sex, especially in those of the clerical profession, probably because they often lead very sedentary lives, and also because they are called upon to speak in public in a tone raised above the ordinary standard."

Cases of the kind under discussion are nowadays commonly classed as examples of some so-called "hysterical affection of the larynx," although in many cases no other indications of hysteria are present. There can be no doubt but that in a very large proportion of instances the sufferers are either delicate young women, or highly sensitive "nervous" subjects of the other sex. At the same time it must be admitted that the true pathology and proper explanation of the affection are at present altogether wanting. Türck[2] and Gerhardt[3] on the Continent, and Mackenzie[4] in this country have of late especially attempted to give precision and definiteness to our ideas respecting the observed phenomena. They have also contributed somewhat to our knowledge of the determining causes of the affection, and the treatment that should be adopted when it is fully established.

Sometimes the aphonia comes on as the result of exposure to cold after extra exertion of the voice. In such case, as suggested by Gerhardt, it may be to some extent analogous to the facial paralysis due to *coup de vent*. Sometimes it appears to be simply the effect of fatigue and incapability for renewed effort. Sometimes it remains after an attack of "sore throat" has altogether passed off; and in such case it may be the effect of indisposition, as it were, on the part of the muscles to resume those natural functions, from the performance of which they have been temporarily restrained by reflex sensibility. Sometimes, again, the determining cause may be mental emotion, from the sudden effect of which the nervo-muscular apparatus of the larynx may have been unable to recover itself. But much more frequently the explanation remains altogether undiscovered.

The affection now under consideration must be carefully distinguished from those forms of laryngeal paralysis with aphonia or hoarseness which are due to the pressure of tumors, aneurism, etc., upon the motor nerves of the larynx.

Treatment.—In some cases, and almost always in such as appear to depend simply upon local indisposition to exertion resulting from the effects of exposure to cold, fatigue, etc., recovery takes place naturally after a certain period of rest. But in many cases, and most constantly, perhaps, in such as are most obscure in their origin, the aphonia may remain persistent during weeks, months, or even years; and then, either as the result of some accidental circumstance, or as the effect of treatment, the voice may be either suddenly restored or gradually recovered. Constitutional treatment of the kind indicated by the general condition of the patient is often beneficial. But in a very large proportion of cases, some local stimulus—some "shake up" as it were—is necessary in order to set the nervo-muscular apparatus in action. Such local stimulus may be supplied in various ways.

In some cases the introduction of the laryngeal speculum, together with all the attendant formalities, is all that is required. Türck appears to have been the first to notice this "method of cure" of aphonia.[1] Trousseau and Krishaber refer to several instances.[1] Three have come under my own observation. One of these may be worth mentioning, inasmuch as it affords an excellent illustration of the manner in which in cases of this kind the voice may sometimes be suddenly regained.

A young lady, about nineteen years of age, was brought to me by her friends, who appeared most anxious about her condition, believing that some very serious disease existed. I was informed that the patient had entirely lost her voice for more than six months, and that all sorts of treatment had been tried, but with no good effect, etc. After a great deal of persuasion, and very many abortive attempts, I at last succeeded in putting the laryngeal speculum into position. I then, in a matter of course tone, requested the patient to say "*Ah, ah.*" Pushing away my hand, she immediately and impatiently exclaimed, in fair natural voice, "How can I, with that thing in my throat?" And then she added, "Oh, dear! I've spoken!" It is almost needless to add that the cure was complete. But supposing that it had happened that some special method of treatment had been in process of application at the moment, what a marvellous cure this would have been!

In some cases the inhalation of strong stimulating or irritating vapors, as those of ammonia or chlorine solutions, proves efficacious; in others the application of solutions of nitrate of silver or sulphate of copper by means of the sponge, probang, or brush, is followed by restoration of the voice. This method of treatment found especial favor with Trousseau, who records many cases illustrative of the good results obtained.[2] It is not improbable that in some cases equally good results might be obtained by the introduction of an *unmedicated* sponge or brush.

Another method of treatment especially relied on by Mackenzie consists in the direct galvanization of the vocal cords. This can be most easily and perfectly accomplished by means of Mackenzie's laryngeal galvanizer or electrode. There can be no doubt of the efficacy of this method. But—without any idea or intention of impugning for one moment the genuineness of the numerous examples from time to time published, in which cases of aphonia of long standing have been stated to have been cured by single, or by a few successive "applications of galvanism to the vocal cords"—it may nevertheless be asserted that the application of galvanism possesses no *specific* virtues in such cases as those under consideration. It simply affords a convenient and very effective method of giving the necessary "fillip" to the nervo-muscular apparatus. Equally good results have been obtained by passing the interrupted current of an electromagnetic battery through the back of the tongue.

[2] Clinique médicale. Op. cit., tom. i., p. 579 et seq.

The method of treatment most recently advocated consists in manipulating (that is pinching and pressing backwards) the larynx; and many cases are recorded illustrating its efficacy.[1]

In conclusion, it may, I believe, be stated without fear of contradiction that the one thing especially necessary is, if possible, to surprise or startle the larynx into proper activity, and it matters comparatively little by what means this effect is accomplished. It must be borne in mind that in these affections there is no perceptible organic disintegration or wasting of the tissues. They appear to be sufficiently exercised for purposes of nutrition during their ordinary respiratory movements, which, as a rule, are carried on normally and without interruption.

Idiopathic atrophy of the muscles of the larynx and *muscular atrophy as the result of disease* are very rare affections. The examples that have at present come under investigation are so few that no satisfactory conclusions can be deduced.[2] It may be well, however, to bear in mind that such cases may from time to time present themselves.

In every case of aphonia, hoarseness, or other alteration of the voice, in which on laryngoscopical inspection one vocal cord only is found to be more or less completely paralyzed, and in which, at the same time, the parts generally are natural in appearance, search should be made for some cause of pressure upon, or interference with, the motor nerves of the affected side of the larynx. If the vocal cord rest motionless during attempted vocalization, attention should be especially directed to the recurrent nerve. If, however, the vocal cord is adducted and abducted more or less normally, but is not duly rendered tense, it may be that the superior laryngeal nerve, or rather its cricothyroid branch, is interfered with. Paralysis of the left vocal cord not infrequently indicates the existence of an aneurism of the arch of the aorta, or of some intrathoracic tumor.

SPASM OF THE LARYNX. SPASM OF THE GLOTTIS.

Spasm of the larynx, attended by the most alarming and sometimes fatal dyspnœa, may arise from various different causes. Many such causes have been already discussed in the preceding pages. Others may depend upon the effects of injuries, or the introduction of foreign bodies into the air-passages (see Vol. I. pp. 695–704 et seq.). Others again may depend upon the irritation produced by the pressure exerted upon the laryngeal nerves by aneurisms or tumors, whether they be "new growths" or simple enlargements of some natural organs, as the thyroid body, lymphatic glands, etc., and whether situated in the neck, or within the thorax. Intrathoracic tumors pressing upon the trachea or bronchi by some reflex nervous influence, and hysteria, tetanus, and certain cerebral affections in some manner altogether inexplicable, may also give rise to spasm of the larynx.

However difficult it may sometimes be to ascertain the cause, the symptoms of this formidable affection are always unmistakable.

Treatment.—If the spasm does not very quickly and very completely subside under simple treatment—and even in absence of all satisfactory explanation of the cause of the attack—tracheotomy should be performed without hesitation. There is far more danger in waiting too long than in operating too soon: and whatever the result, the conscientious surgeon may always feel assured that it is better to have made an unnecessary incision into the windpipe than to have allowed his patient to die for want of one.

DISEASES OF THE THYROID GLAND.

By Holmes Coote, Esq.

Revised by J. Solis Cohen, M.D.

The thyroid gland, one of the vascular bodies without ducts, consists of two lateral lobes, connected by an isthmus, which crosses in front of the three upper rings of the trachea. Hyrtl affirms that he has met with instances of complete congenital absence of the isthmus; and in aged subjects it is sometimes so far absorbed as to be scarcely distinguishable, the two halves of the gland appearing to be united only by areolar tissue. The proportion of the gland to the entire body diminishes with age. In new-born infants it is 1:300; at the end of the first month it is 1:1200; in adults it falls to 1:1800.[1] It is supplied by four, and sometimes by five, large arteries, branches of the carotid and subclavian trunks; the fifth artery, when it exists, lying in the mesial line of the trachea. The organ lies, moreover, in close contiguity to the great vessels and nerves of the neck.

Few surgeons believe that the entire thyroid gland has ever been successfully extirpated, although cases are so related by Desault, Roux, Gooch, Vogel, Theden, Hedenus, and others.

[In the United States, there is no doubt upon this point, albeit the profession are not generally prepared to endorse the operation under the circumstances in which it is most frequently performed. Not to be invidious, the names of the two Warrens of Boston, are especially associated with the operation, which has been successfully performed in many other portions of the country likewise.]

Dr. Hedenus speaks of six successful cases of removal. The operation, as recorded by himself, is as follows:—An incision was made from the os hyoides to the top of the sternum, and the skin reflected from each side to the extent of two inches. The sterno-hyoid and thyroid muscles, which were adherent to the tumor, were cut through in consequence of the hemorrhage following an attempt made to reflect them. He next separated the swelling above and below from the sterno-cleido-mastoid and omohyoid muscles, and also from the jugular vein and carotid artery (to which it was closely adherent), until he freed it as far as the point where the thyroid arteries originate. He then tied the superior and inferior thyroid arteries close to the tumor, and, on account of the free anastomosis, applied to each vessel two ligatures, and divided it in the interspace. The more deeply the dissection now extended, the more hazardous did it appear. Every four or five lines he was obliged to tie two or three arteries; a proceeding which was effected with great difficulty. After most cautiously dissecting to the base of the tumor, which was attached to the thyroid cartilage and the three upper rings of the trachea, he met with so many arteries, for the most part as large as the radial or ulnar, that in order to prevent further loss of blood, he decided to tie the base of the tumor, and to cut away all beyond the ligature. He accordingly first passed a needle, armed with ligatures, through the base of the tumor, and tied the ends; and next passed another ligature round the entire base, and removed as much as he thought proper. Some local applications, of no importance, were applied. During convalescence hemorrhage occurred, which was arrested by sprinkling the wound with gum-arabic. On the eighth day the ligatures came away. The patient ultimately recovered, and left the hospital well![1] These proceedings are scarcely considered admissible in modern surgery.

[Thyroiditis.

Acute inflammation of the thyroid gland is rare. It may occur even after unusual exposure to inclemency of weather, and even by extension of inflammatory processes from intra-laryngeal inflammations, such as occasionally accompany the degeneration of neoplasms. The symptoms comprise local swelling, and the usual evidences of inflammatory action. Resolution may occur, or abscess follow according to circumstances. It is also possible, as in one case under the reviser's care, that the dyspnœa induced by the tumefaction, may be sufficient to demand the prompt performance of tracheotomy and the introduction of the canula.

---

[1] Gräfe's Journal, b. ii., p. 237.

The treatment is that ordinarily pursued for acute external inflammations.]

[BRONCHOCELE.]

The most frequent affection of the thyroid body is chronic enlargement, or hypertrophy, to which the term "bronchocele" is commonly applied. But under this head are included several morbid changes, all allied to one another in being developments of the natural component tissues of the organ.

A simple bronchocele consists in a uniform enlargement of the thyroid body in all its parts. The texture of the gland is healthy, except that it is coarser than that of a thyroid gland of ordinary size. Very frequently numerous cysts of one or two lines in diameter are found filled with a viscid fluid, or some, fewer in number and of larger size, partitioned and filled with a thin watery or bloody fluid, and scattered irregularly through its substance. As the enlargement proceeds, it may surround and compress the trachea and lower part of the larynx. [Severe dyspnœa is sometimes the result of compression. The involution of the trachea is recognizable, at times, on larygoscopic inspection. Tracheotomy is admissible in these instances, provided a canula can be inserted below or beyond the point of compression. In some instances, the operation is practised right through the gland.] A case is recorded by the late Mr. Howship, in which the jugular vein passed through the substance of the gland, and the patient suffered greatly from congestion of the head. The two lobes are rarely equally increased in size, the right being more commonly the larger: sometimes, it is said, the middle lobe, or pyramid, is principally affected. In this country [and in America] bronchocele is more common in women than in men. Cases occur in which young girls, from seventeen to twenty-four years of age, are subject to considerable enlargement of the thyroid body at each menstrual period; the swelling subsiding as that function subsides. [A similar condition is not infrequent during successive pregnancies.] I had under my care a young lady, in whom this thyroid enlargement became permanent, after the abrupt cessation of menstruation, caused by her being exposed to cold and wet during a stormy passage at sea. Mr. White Cooper has observed that in persons subject to this affection the eyes are often more than usually prominent. When of moderate size, the disease can be easily recognized, both by its position and by its following the movements of the trachea and œsophagus. It rises if the patient be directed to swallow. But when of larger size it may be known as being unlike anything else. It may be raised with every pulsation of the carotid artery, or hang down in front of the chest, so that it cannot be concealed by any sort of clothing.

In the severer forms bronchocele or goître is endemic. It prevails in Derbyshire, Nottingham, and the chalky parts of England; in the valleys of the Alps, Apennines, and Pyrenees. Postiglione remarks, that in Savoy, Switzerland, the Tyrol, and Carinthia, there are villages in which all the inhabitants, without exception, have these swellings.[1] The cause commonly assigned, namely the use of melted snow, or of water impregnated with calcareous or earthy particles, is unsatisfactory. Capt. Alexander Gerard, in his account of Korrawur, in the Himalayas, says, "although the Korrawurrees can get nothing but snow for some months in the year, they are not so subject to goître as the people who live in the damp grounds in the forest at the foot of the hills, where there can never be any snow-water. The water which flows from the hills of lias, forming the Asiatic side of the Dardanelles, is impregnated with lime; but yet during a residence of many months I did not notice the prevalence of goître." This idea has been successfully refuted by Alibert; and Foderé has explained how the disease cannot be referred to the use of any particular kind of food. Dr. Guggenbühl, the founder of the Cretin Hospital, remarks that both cretinismus and goître, which may exist either conjointly or separately, prevail in deep valleys, where the air stagnates, and the population, scanty in numbers, becomes deteriorated by frequent intermarriage. Cases of goître and idiocy removed to an elevated position, and properly nurtured, are first made to thrive bodily, and then are susceptible of mental improvement; and he particularly relates the case of a cretin child, who after having passed a life of apparently complete insensibility to external objects, gave suddenly the first indication of aroused consciousness, after proper treatment, by exclaiming, "Die Sonne!" (the sun), as the light of day fell on the spot where he was seated. Humboldt says that persons afflicted with bronchocele are met with in the lower course of the Magdalena River, from Honda to the conflux of the Cauca, in the upper part of its course, between Neiva and Honda, and on the high country of Bogota, six thousand feet above the bed of the river. The first of these three regions is a thick forest, while the second and third present a soil destitute of vegetation; the first and third are extremely damp, the second is peculiarly dry; in the second and third the winds are impetuous, in the first the air is stagnant. To these striking differences we will add those relative to temperature. In the first and second regions the thermometer keeps up all the year between 71° and 73° F.; in the third it ranges between 37° and 62° F. The waters drunk by the inhabitants of Maraquita, Honda, and Santa Fé de Bogota, where bronchoceles occur, are not those of snow, but issue from rocks of granite, freestone, and lime. The temperature of the waters of Santa Fé and Mompox, drunk by those who have this disease, varies from nine to ten degrees. Bronchoceles are the most hideous at Maraquita, where the springs, which flow over granite, are, according to Humboldt's experiments, chemically more pure than those of Honda or Bogota, and where the climate is much less sultry than upon the banks of the Magdalena River.[1]

---

[1] Memoria sulla Natura del Gozzo, p. 22.

Dr. John Webster has favored me with some manuscript notes bearing upon this subject. He says that, according to information collected from reliable sources, there are 500,000 goîtrous persons in France. Some localities in that country are very remarkable for the large number so designated. For example, in a town of Lorraine, having recently 736 inhabitants, there were recognized 164 affected with goître, of whom 143 were females. Of the 164 goîtreux, comprising both sexes, 105 lived in houses having a northern exposure, while only 59 inhabited dwellings fronting the south, and thus enjoying more sunshine than the others. At Rosieux, also in Lorraine, it is reported that every indigent female is goîtrous. In the arrondissement of Schalstadt, situated in the Lower Rhine department, 658 goîtreux were lately registered. A still more remarkable instance of the frequency of the disease occurs at St. Aubin, near Elbœuf, on the banks of the Seine, not far from Rouen, where one female in every 16 of the total population has goître more or less developed. Other places in France might be named where the affection is very prevalent.

In Piedmont and Savoy, especially the latter, goitre is very rife. By an official report, continues Dr. Webster, published a few years ago, there were 18,462 simple goîtreux, besides 3909 cretins. Various mountainous districts in Europe are afflicted with this complaint, which, however, always disappears before civilization. It becomes rare as persons are better clothed and fed, and are not compelled to intermarry. Prior to 1818, goître was very common in the Swiss canton of Valais, and particularly in several secluded valleys near Martigny. In that year, from the bursting of a lake high up in the mountains, a valley not far from that town was completely devastated; houses, trees, cattle, and people being carried away by the flood. However frequent in this part was the prevalence of both goître and cretinism before the event. it was remarked that subsequently it nearly entirely disappeared, and the reason seemed the following. Before the great inundation, the soil of the valley was always wet, marshy, and unproductive. By the overflowing of the lake a mètre of good vegetable mould was brought down from the higher regions; the natives were obliged to exert themselves in the cultivation, whereby their physical status was much ameliorated, and the supply of food materially augmented.

At Caneles, near the Cordilleras, in North Mexico, many of the inhabitants are grievously affected. Authorities state that half of those employed in the mines are goîtrous, though generally only on one side of the neck. It is affirmed that children born of such parents are frequently idiots, or deaf and dumb.

In the treatment of bronchocele we should be particular to put the patient under circumstances favorable to recovery. In females, the menstrual function generally requires regulation; and a low damp situation should, where possible, be changed for a more airy spot. Blisters have been applied, and kept open; frictions have been recommended; the application of emplastrum ammoniaci cum hydrargyro, electricity, etc., but without much effect.

The remedy most relied on at the present day is iodine, which was first given in the form of burnt sponge; and is now employed both internally and locally, in the different forms admitted into the pharmacopœia. The iodide of potassium may be administered in doses of two or five grains, or even more, three times a day. If more than three grains are given at the commencement, the medicine is often removed in its excess by the secretion of the kidneys. In large doses it is apt to excite salivation. and to irritate the stomach. Iodine was discovered in 1813, by Courtois, manufacturer of saltpetre in Paris; but Dr. Coindet was the first to introduce it into medical practice for the cure of bronchocele. Shortly after its efficacy had been established, Dr. Fyfe, of Edinburgh, discovered the presence of iodine in burnt sponge.

[The reviser has had considerable success in treating goitre of recent origin, by local applications of a saturated solution of iodoform in ether, chloroform or collodion. The collodion solution possesses the advantage of exercising an equable compression upon the exterior of the gland, which appears to be additionally salutary. When the volatile ether or chloroform evaporates, a well-distributed layer of iodoform remains, a portion of which is undoubtedly absorbed through the skin, and thus exercises its resolvent powers. The applications are usually repeated daily, with occasional intermissions, whenever the skin becomes too tender for such frequent repetition.

---

[1] Humboldt, in Journ. de Physiologie, par Majendie, tom. iv., p. 116.

Appropriate constitutional treatment is likewise instituted, iodoform being often substituted for the iodides more generally resorted to.]

Cases of enlargement of the thyroid body, demanding the application of ligatures to the nutrient arteries, must be considered exceptional, and modern surgery somewhat avoids the operation. In a case recorded by Sir W. Blizard, the patient died from the effects of hospital gangrene;[1] but a case reported by Walther, of Landshut, was successful.[2] The superior thyroid arteries were successfully tied by Mr. Coates, of Salisbury.[3] Mr. Skey observes:[4] "While on the subject of tying arteries in the region of the neck, I have referred to the operation of tying the superior thyroid artery as performed by Sir W. Blizard, by Mr. Earle, and others. It is an operation the performance of which is perfectly justifiable, and, as I can testify, is attended with marked diminution of the enlarged structure, if this be the object to be attained: but the relations of the inferior thyroid arteries are so much more complicated, and the artery itself lies so deeply imbedded in the structures of the neck, that I conceive its exposure without danger to be almost impossible." Thus the question stands; the general feeling being by no means favorable towards the operation.

Dr. Murnay speaks highly of the treatment of bronchocele by strychnia. The first case in which he used it was that of a lady aged thirty, who had had good health up to four years previously, when the catamenia became irregular and were attended with great pain on each periodic return. She assigned as the cause of the thyroid tumor great distress of mind and disappointment. When Dr. Murnay saw her, the disease was of six months' duration; the right lobe of the thyroid gland was fully as big as a turkey's egg, extending laterally so as to press on the right carotid artery and jugular vein; a strong pulsation was felt in the tumor, and a purring thrill was communicated to the hand. She had no palpitation of the heart; but she complained of headache, and of a buzzing noise in the right ear; she imagined there was a slight enlargement of the right eye, and that she felt a sensation of fulness in it. The tumor at times impeded deglutition, and occasionally her breathing also. After a fair trial of the usual remedies, strychnia was administered in the dose of $\frac{1}{16}$ gr. three times a day. At the end of a fortnight there was great improvement, and ultimately the gland regained its normal size. The second case was that of a housemaid, the enlargement having lasted twelve months, and both lobes being involved. There was great palpitation of the heart, pulse 130, eyes prominent, catamenia irregular, tongue large and flabby, and coated with a yellow fur in the centre; bowels constipated, acting only once a week. In this case the medicine was ordered in a fluid form; one grain was dissolved in seven drachms of water and one of dilute sulphuric acid. She was to commence with five minims three times a day, and to increase to twenty. On the tenth day of taking the medicine, a great flow of menstrual discharge came on, lasted a few days, and returned in a week. The treatment was continued, and soon after the gland began to shrink. The third case was that of a young lady aged fifteen, in which at the time of the report the symptoms were progressing favorably.[1]

Mr. Hey, of York, has treated bronchocele successfully by seton. The patient was a young lady twenty-one years of age, who had suffered from bronchocele from her earliest infancy. Mr. Hey passed a skein of silk through one half of the gland, commencing at the upper part, in the median line, and, taking as nearly as possible a semicircular direction, brought it out at the corresponding point below; thus embracing half the tumor, at a depth of from three-quarters to one inch, so that the seton was fairly established in the substance of the gland. The patient did not seem to suffer pain, and there was no hemorrhage of consequence. For the first five weeks no material change took place; the discharge was slight, and it was found necessary to use savine ointment. In the course of the sixth week the patient suffered from a feverish attack; on the third or fourth night after the fever she was seized with a cough of most distressing character; she became delirious, with brown and dry tongue; this condition lasted forty-eight hours. The seton began to discharge a thin, dirty-looking, and most offensive matter, which relieved the irritation about the windpipe, and the delirium subsided. By degrees the discharge became purulent, and ultimately all signs of thyroid enlargement disappeared.[2] Mr. Hey remarks that this operation was known a century ago;

but Dr. Quadri, of Naples, revived it, and practised it to a considerable extent about the years 1817-18. Mr. Copland Hutchinson tried it in 1819.[1] Mr. T. A. Thompson and others have followed, with generally favorable results. Still the nature of the symptoms here recorded point clearly to chances of risk, and a cautious practitioner should well weigh the necessity of operating at all.

[Injections of tincture of iodine, solutions of carbolic acid, tincture of the chloride of iron, solutions of ergot, and other agents, are sometimes practised with success, in hypertrophic goître as in the cystic variety. Interstitial injections are not devoid of danger, and are sometimes productive of death by entrance of air into the venous circulation, or by thrombosis and embolism.]

M. E. Collin, médecin-major de 1re classe, records the particulars of a remarkable attack of acute goître in the garrison at Briançon during the year 1860. The 87th regiment of the line arrived at Briançon on October 22, 1859. During 1860 it represented the garrison of the place, comprising an effective force of 1062 men. During the year the regiment sent to the infirmary 55 cases of goître. Of these 55, there were 53 acute cases contracted at the town. The attack nearly always commenced after six months' residence. The five months most fertile in the generation of goître were from May to September. M. Collin has called attention several times to the rapidity with which this disease may manifest itself. In certain subjects much predisposed, eight days sufficed for its formation.

Of the 53 goîtres, there were 8 median, 2 unilateral, 27 bilateral, and 16 three-lobed. Of the 27 bilateral goîtres, 20 were on the right side; and of the 16 three-lobed, 10 were also on the right. This latter point confirms the opinion of Alibert, and is supported by nearly all the specimens in the Hunterian Museum. No remedies were found of any avail; and M. Collin very properly recommended either a rapid change in the regiment, or an entire change in the locality of the station. He adds that during winter the ground is constantly covered with snow; and that during that season there is no proper place for exercise.[2]

Instances are upon record in which bronchocele has proved fatal, by compression of the trachea. One of the latest cases is recorded by Dr. Dickinson.[3] The patient was a tailor aged seventeen. For some time he had had palpitation of the heart, and about eighteen months before his death he noticed a swelling in the position of the isthmus of the thyroid gland. The swelling extended laterally, so as to occupy the sides of the neck, and he then began to have fits of shortness of breath. In the attacks of dyspnœa the air passed with a hissing sound, as if from constriction of the larynx. He was admitted into St. George's Hospital, where he one night died suffocated before tracheotomy could be performed. Upon examination after death, it was found that the compression of the trachea, which was very great, commenced at about two inches below the vocal cords, and extended downwards for two or three inches. A preparation, exhibiting in a striking manner the enlarged thyroid gland surrounding and compressing the trachea and the lower part of the larynx, is preserved in the Museum of St. Bartholomew's Hospital. Mr. Macwhinnie[1] relates the case of a patient aged seventeen, attended by Mr. M'Crea of Islington, where death ensued under symptoms similar to those of strangulation.

The enlargement of the thyroid gland, which has been noticed not uncommonly in pregnancy, and quite independently of the conditions usually considered to be favorable to the production of goître, is not usually dangerous; but M. Guillot notices two cases under his own care, which show that it may prove perilous to life itself.

A lady æt. thirty, in easy circumstances and of excellent health and constitution, found her neck, during a first pregnancy, become the seat of a slowly-increasing enlargement. During a second pregnancy, in 1835, it increased again and became troublesome. In 1858 M. Guillot saw her with M. Trousseau, as the respiration was much impeded. A few days afterwards, the patient being nearly asphyxiated, laryngotomy was performed with immediate relief, but death ensued in two days.

The second case was that of a young woman aged twenty-nine, the mother of two children. Both respiration and voice were embarrassed, and she was liable to suffocative paroxysms. These symptoms had come on gradually from the time of her first pregnancy. She was admitted into the Necker Hospital, where one of the paroxysms of dyspnœa terminated fatally. The thyroid gland had nearly acquired the size of a human brain; the tissue was healthy in appearance, and there were numerous small cysts scattered throughout its substance.[2] The author regards the disease as one of the manifestations of the excessive production of fibrin during pregnancy.

Dr. Herbert Davies exhibited at the Pathological Society of London, May 21, 1849, both the thyroid and the thymus glands much hypertrophied, taken from a boy aged sixteen, who died suddenly from a spasmodic affection of the larynx. He had noticed the swelling of the neck about the age of fifteen; the enlargement increased rapidly about four months previous to his death, and it produced a sensation as if he were "breathing through a sponge." On examination, the thyroid, thymus, and bronchial glands were found much enlarged; in the last there was a deposit of tubercle. On microscopic examination of the thyroid gland, it was found to consist of the usual vesicles, containing a fluid in which were a large number of corpuscles, the majority of which were smaller than the blood-disks.

Pulsating or exophthalmic bronchocele.—A peculiar variety of bronchocele, distinct from the ordinary goître, and to which various names have been applied, may be here noticed; though, as it forms but one link in a long chain of morbid symptoms, it would be out of place to describe fully the disease, of which it forms but a part, among the affections of the thyroid gland. It is almost invariably associated with palpitation of the heart and a prominent condition of the eyeballs, and hence have arisen the various names under which these combined symptoms have been described: as "goître exophthalmique," "affection of the heart and thyroid gland," "anæmic exophthalmos," "maladie de Graves," "maladie de Basedow,"—according to the theory of the origin of the disease which each writer adopts, or the name of the authors who were supposed to have first described it. It occurs more commonly in females than in males, though it is by no means confined to the former sex. The characters of the disease are very well marked, and are thus enumerated. The first symptoms are usually palpitation of the heart and habitually rapid pulse, with other signs of nervous debility; and these are followed at a longer or shorter interval by enlargement and pulsation of the thyroid gland, with violent beatings of the carotid arteries. After these symptoms have existed for some time,—and in some cases it is said, before the enlargement of the thyroid gland,—an unnatural prominence of the eyeballs begins to be perceptible; and this gives to the patient a wild or startled, and occasionally almost maniacal expression. In a case related by Dr. Stokes,[1] "the tumefaction continued to increase, until the globes of the eyes appeared to protrude from the orbits, looking downwards and forwards, and exhibiting a zone of white sclerotic round the entire of the cornea of at least two lines in breadth. The lids could only be half closed; and the appearance of this lady during sleep, with those great brilliant eyes yet open, can never be effaced from my memory."[1]

The enlargement of the thyroid gland is peculiar. In one of Dr. Begbie's cases, which may be taken as a type, it was soft, smooth, and elastic, and of equal character throughout, presenting the form of hypertrophied gland, and had rapidly developed itself to its present size—that of three or four times the magnitude of the gland in health; but it was subject to remarkable variations in this respect, according to the state of mind, rest, or palpitation. It appeared to be highly vascular, and conveyed to the touch the sensation of an erectile tumor.[2] There is commonly also a purring thrill to be felt by the fingers, and a loud and sometimes musical bruit to be heard through the stethoscope. Indeed, some years ago a case, in which there existed this condition of the gland, was mistaken for an aneurism, and (though fortunately for the patient the nature of the disease was discovered in time) a day had been appointed for tying the carotid artery.[3]

Together with the pulsation of the thyroid gland and of its dilated main arteries, the carotids beat violently, and often with a double pulsation and loud bruit; and the patient complains of distressing sensations of suffocation, hammering in the head, vertigo, tinnitus aurium, etc. In a case recorded by Sir H. Marsh, the patient could feel the whizzing in her neck, and it formed one of her most distressing symptoms. Sometimes also the pulse in other arteries than the carotid is unusually jerking and large. In one of Dr. Stokes's cases the patient complained of violent pulsation of the abdominal aorta; and in a case which Dr. C. J. B. Williams mentioned at the Med.-Chir. Society,[4] there was enlargement of the arteries of the forehead, face, and neck. In many cases, however, a marked difference in the pulsation of the carotids and of the radial arteries has been noticed; that of the former being violent and jerking, that of the latter comparatively feeble.[1] Sometimes large veins can be seen ramifying over the enlarged thyroid gland; and the external jugular and other veins of the neck are at the same time much distended. The heart beats quickly, and upon the least excitement violently; and at its base and in the large arteries a bellows-sound is almost always to be heard through a stethoscope. The pulse, indeed, habitually rapid, often reaches 130 to 140 beats in a minute.[2]

---

[1] Diseases of the Heart and Aorta, 1854, p. 285.

[1] Dr. Stokes supposes that the prominence of the eyeballs depends on an increase in the vitreous and aqueous humors; but the majority of observers, probably more correctly, think that the prominence is caused by some morbid condition of the structures situated in the orbit, behind the globe. What this morbid state is, remains, however, still uncertain. Effusion of serum, increase of post-ocular fat and cellular tissue, congestion of the orbital veins, etc., have been assigned by different writers as causes of the protrusion.

[3] Diseases of the Heart and Aorta, by Dr. Stokes, p. 279.

[4] Lancet, Dec. 8, 1860.

From the foregoing account, it will be readily seen that this disease is very different from ordinary goître; and indeed its diagnosis from this or from any other malady is not difficult. These are the chief points of distinction from common bronchocele: 1. The size of the tumor formed by the enlarged gland varies considerably with the general condition of the patient as to rest or excitement, and their effect on the heart's action; 2. The appearance of the disease is independent of endemic influences, so powerful in the production of ordinary goître; 3. The tumor rarely becomes large enough to cause any great deformity, though Dr. Stokes says he has seen two cases in which this was produced in a considerable degree; 4. Dr. Graves says that it differs also from goître in its size becoming stationary just at that period of growth at which the last-named disease usually increases more rapidly; 5. The purring thrill and loud murmur in the tumor, as well as the other general symptoms—the palpitation, the prominent eyeballs, the jerking carotids, etc.—will be abundantly sufficient for confirming the diagnosis.

Notwithstanding the apparent urgency of the symptoms, this disease is very rarely fatal, unless accompanied with organic disease of the heart, or some other serious complication. Comparatively few opportunities of examining the condition of the thyroid gland, after death, have therefore occurred; and these have been for the most part in those who died from some attendant malady, rather than from the peculiar assemblage of morbid symptoms which by themselves make up the disease.

The appearances, therefore, which have been observed in the heart, etc., after death, in the few cases on record, must not be taken as representing those which ordinarily exist; but must be checked by the observation of the far larger number of cases in which complete recovery has ensued on proper treatment. The appearances, however, which more immediately concern us—those in the thyroid gland, namely—are probably characteristic.

In 1841, Sir H. Marsh communicated to the Pathological Society of Dublin an account of a patient who suffered from this disease, and who died from gangrene of the extremities, preceded by erysipelas and anasarca. The thyroid gland was irregularly lobulated on the surface, the lobules or cysts containing a quantity of clear fluid. The right internal jugular vein was much dilated, and measured, when emptied by puncture, an inch and a half across. One of the enlarged lobes of the thyroid body lay over the carotid artery. Both auricles, especially the left, were much dilated. The left ventricle was somewhat dilated and hypertrophied. The auriculo-ventricular valves, on both sides, had thickened margins; the disease apparently proceeding from depositions of fatty granular matter under the membrane. The right valves were more affected than the left.[1] In another case, that of a woman who died from apoplexy, and who, at the time of her death, suffered from this disease, the thyroid arteries, which during life could be felt pulsating strongly, were found greatly enlarged and remarkably tortuous. The thyroid gland was enlarged. The left ventricle was greatly hypertrophied, and its cavity much dilated.[2] In a case of Dr. Begbie's, the thyroid gland was enlarged to three times its normal bulk from hypertrophy. The heart was somewhat enlarged, from slight dilatation of the right cavities. The walls of the right auricle were very thin. The valves were healthy. Various other organs were more or less diseased.[3] In another case recorded by the same author, and in which the patient died from heart-disease, general dropsy, etc., "the sterno-hyoid and sterno-thyroid muscles were much thinner and broader than natural, from being stretched over the thyroid body, which was of large size. The external jugular veins were normal; the internal jugulars were large; the left one, when slit open, measured an inch and a half across at a level with the cricoid cartilage. The thyroid body was of large size, but was not weighed; its weight, however, might be computed at four or five times the natural weight. Each lateral lobe measured an inch and a half in breadth, and was of a corresponding thickness. This great size was not partial, but general; and although the isthmus was comparatively larger than the lateral lobes, there was complete symmetry of both sides. It was of a dusky-red color, smooth, and well-defined, and slightly irregular on its anterior surface; but still retained the natural convex and semilunar form of the organ, when in a state of health.[4] Several other organs were diseased.

The prognosis in those cases—the most frequent—in which there exist no signs of grave organic disease in the heart or other organs is very favorable, though a long time often passes before the characteristic features of the disease entirely disappear. In favorable cases, the heart, becoming less excitable, again recovers its former steady and healthy action ; and an improvement in the state of this organ seems to be usually the first step towards recovery.[1] Then follow recession of the eyeballs within the orbit, and gradually lessening of the thyroid tumor, with loss of its pulsation, and, it may be, hardening of its substance ;[2] and, accompanying these are improvement in the general health, and commonly, after a longer or shorter time, perfect recovery.

The immediate causes of the disease are not very well defined ; but they appear to include almost any of those circumstances which lead to general ill-health and anæmia, although in some cases the patients are tolerably healthy-looking or even plethoric. Dr. Begbie, however, thinks that even in these there is probably an unhealthy condition of the blood ; and adds, "I have seen no instance of the disease in which the general and physical signs of anæmia were not more or less completely developed, and no case in which an adequate cause of that condition was not furnished in its history ; nor any one in which a marked mitigation, or complete removal of the symptoms, has not taken place under a plan of treatment calculated to overcome the blood disorder."[3] Amenorrhœa, long-continued hemorrhage from piles, bilious diarrhœa, want of rest, and many other similar causes, have been assigned in different cases. Dr. Stokes says, "In young women, mental anxiety and the effect of terror may produce it. I have known a remarkable instance of the latter cause inducing the disease in a lady who had previously been healthy." In a few cases the disease appears intimately associated with organic disease of the heart ; but this can be by no means considered essential, and the cardiac disease is supposed by many, when it exists, to follow rather than precede the symptoms which have been described, and to arise from long-continued functional disorder of the organ.

There has been almost as much difference of opinion concerning the nature of this disease as there has been agreement concerning its symptoms, prognosis, and treatment. Dr. Begbie thinks that the essence of the disease consists in a vitiated or impoverished condition of the blood, and that this condition, acting directly on the cardiac nerves, excites the heart and vessels to over-action ; that the anæmic palpitation thus produced is followed by the characteristic symptoms, and, if not removed, issues in organic change of the heart, in enlargement of the great vessels, in induration and structural degeneration of the thyroid gland, etc. Dr. Stokes supposes that the disease is a special form of cardiac neurosis, which may lead to organic disease, and that the nervous excitement is possibly propagated to the arteries of the neck, as he thinks that their pulsation is more than can be accounted for by the force of the heart. Prof. Laycock[1] thinks the symptoms are due to neurosis of the cerebro-spinal tract, or rather of several vaso-motor centres in the spinal cord. The bronchocele (which is essentially a dilatation of the vessels of the thyroid gland) he thinks is due to a lesion of a paralyzing kind of the trunk of the sympathetic. Dr. J. O. Fletcher is of opinion that we must look to the nervous system, and especially to the brain for the cause, and that the disease is "hyperneuria," induced by sleeplessness, anxiety, etc., impairing digestion and assimilation ; "secondarily interfering with the normal nutrition of the nerve-centres, causing a state of hyperneurosis with want of power, which induces imperfect secretion by some organs, and, as a necessary consequence of this, if long continued, causes organic changes."[2] Dr. Handfield Jones : that the fundamental malady is debility, especially of the nervous system, which, by affecting various vaso-motor nerves, gives rise to the several symptoms.[3] M. Trousseau : that it is a neurosis, having its proximate cause in a change of the vaso-motor apparatus, and that the anæmia follows, rather than precedes, the characteristic symptoms.[4]

The proper treatment is very definitely pointed out by the causes and symptoms of the disease. To remove those conditions (if they still exist) which appear to have been important elements in the first production of the disease, as hemorrhage, over-exertion of mind or body, etc.—to allay the excessive action and irritability of the heart by digitalis, morphia, hyoscyamus, and similar drugs—to improve the impoverished or vitiated blood by tonics, especially iron—to place the patient in favorable conditions, as far as is possible, for good air and perfect rest,—are the obvious and most important general methods of treatment, the details of which must be decided separately for each case. Iodine, whether taken internally, or applied to the surface of the swollen thyroid gland, appears to be by itself of very little use. [Iodoform internally, as first pointed out, I believe, by Dr. Carpenter, of Pottsville,[1] is often peculiarly efficacious in the treatment of this form of goître; apparently by some influence on the nervous system, rather than by its resolvent properties.] The application of ice appears in some cases to be very beneficial. It does not often happen that immediate danger is caused by the pressure of the enlarged thyroid body on the trachea; but M. Trousseau relates such a case; and the patient, a boy about 14 years old, was apparently saved from suffocation, or, at least, from undergoing tracheotomy, by venesection, by the application of ice to the neck, and by the administration internally of digitalis.[2] Three weeks afterwards he could walk more than two miles, and, when M. Trousseau last saw him, he had almost completely recovered.

Dr. Graves ingeniously suggests that the globus hystericus, so commonly attendant upon nervous palpitation, and so often referred by the patient to the situation of the thyroid gland, may arise from swelling of this body and pressure on the trachea; and that it is not, therefore, a purely nervous sensation.

Acute inflammation of the thyroid body is rare. Sir T. Watson remarks that this gland "does not seem very prone to inflame; and probably Dr. Copland is right in his opinion that inflammation occurs spontaneously in this organ in scrofulous persons only."[3] I have met with one instance of the disease.

An old woman, incurably insane, died in Bethlehem Hospital, December 22, 1846. Before death, for some days, she had experienced great difficulty in swallowing, and had objected to take food. On examination of the body, it was found that the skullcap was thicker and heavier than natural, and the brain was congested with blood. There was diffused purulent infiltration for one inch in length, and half an inch in breadth, affecting the cellular tissue of the œsophagus just where it winds round to get in front of the descending aorta. The left lobe of the thyroid body was much enlarged, and occupied by cysts of various sizes. There was purulent infiltration diffused throughout the whole organ, but more extensive on the left side. The cysts contained flakes of thick fibrin mixed with fetid fluid. The œsophagus was contracted in that spot around which the pus had been effused. There was no other morbid appearance.

Mr. Turner, of Kensington, has related some cases of *suppurating cysts* of the thyroid body, treated by free incision; in one case the cyst-wall came away, and, reasoning from this experience, he proposed, as a method of treatment, to obliterate the cysts formed in this gland by inflammation artificially excited in the following manner: The skin covering the cysts was gradually destroyed by repeated applications of caustic potash rubbed over a space equal in size to a florin; then a blunt-pointed director was introduced, and pushed about so as to excite vascular action, in consequence of which suppuration ensued, and the cavity slowly contracted. He put this method into practice in two cases, the particulars of which are related in the Medical Times and Gazette, Jan. 20, 1855. We must accord merit to this surgeon for the care with which he conducted his cases.

In 1841, the late Mr. Vincent had under his care, in St. Bartholomew's Hospital, a woman, 48 years old, with a tumor in front of the neck as large as the head of a child of two years. The tumor contained fluid, which was twice withdrawn with a trocar. The fluid first evacuated resembled serum, but coagulated spontaneously; on the second occasion it was mixed with blood. After the second operation, the cyst inflamed, and discharged grumous and sanious pus; but it also enlarged quickly, and the patient died unexpectedly from suffocation. On examination after death, it was found that nearly the whole of the right lobe of the thyroid body was occupied by a cyst, the walls of which were two lines in thickness; the cavity was full of lymph, pus, and blood; the sudden death was due to a discharge of a great part of its contents into the pharynx and larynx, through an ulcerated aperture into the former.[1]

In reference to this subject Flajani says:—

"I was once called to assist a gentleman, 40 years of age, brought to death's door by a bleeding, which arose from the application of caustic to the fore part of the neck. As tourniquets, bandages, etc., proved quite ineffectual, it was indispensable to make pressure on the part with the finger of an assistant for twenty-four hours, ere the hemorrhage could be stopped; a copious suppuration ensued, and it was three months before the part healed. I was likewise present," says he, "at the opening of a similar but larger swelling in the same situation, the patient being an elderly person, who had suffered from the disease for several years. The incision caused the evacuation of a small quan-

tity of serum contained in the cellular membrane; but the following day the tumor inflamed, the difficulty of respiration increased, and for some days the patient was in great danger. At length suppuration was established, followed by destruction of a great deal of the cellular membrane and several sinuses. The patient lost his life; and on examination of the body, the lungs were found tuberculated; an effect of the impediment to the circulation of the blood through the smaller vessels of those organs."[1]

I have succeeded in producing the complete obliteration of a thyroid cyst, with corresponding diminution in the size of the swelling of the gland, in a young married woman, healthy, and of temperate habits, by means of the injection of iodine in the usual proportions of one drachm of the tincture to five of water. But whoever undertakes such an operation should bear in mind the numerous complications which may await him; as well as the fact that in some instances the hemorrhage has been so severe as to demand the application of a ligature to the carotid artery.

Two cases of *cancer* of the thyroid body have been recorded by Dr. v. Franque.[2] Both patients were between forty and fifty years of age, and in both instances there was found further morbid deposit in various organs. In the left lung of the first case there were noticed old tubercle in the upper lobe, and cancerous deposit in the other parts. In the second case the viscera were very generally affected.

The same disease has been described by Mr. Cæsar Hawkins in the Medical Gazette, 1843. The first case, seen in 1837, might perhaps be somewhat doubtful, from want of post-mortem examination; but four other cases were verified. The disease commenced between the ages of forty-five and sixty. In one instance the parts adjacent to the pharynx and œsophagus were infiltrated by cancer. There was a large ulcer on the œsophagus, and the right internal jugular vein was closely adherent to the tumor. I have seen a similar case in St. Bartholomew's Hospital.

In such cases none but palliative remedies are of any avail; but the pain and distress in breathing may be greatly allayed by the employment of the hypodermic injection of morphine.

In conclusion, I may repeat the words of Rokitansky: "If we except serous, fibrous, cartilaginous, and bone-like productions, all other new formations in the thyroid gland are extremely rare. Tubercle is scarcely ever seen, and cancer in its medullary form is in the highest degree exceptional."[1]

APNŒA (ASPHYXIA).

By George Harley, M.D.

Revised by J. Solis Cohen, M.D.

From Suffocation, Hanging, Drowning, Chloroform, Poisonous Gases, etc.

As the chief characteristic of the mode of dying about to be considered is the continuance of the heart's action after the cessation of the respiratory process, in order to be logical as well as philosophical in the treatment of the subject it is necessary to abandon the old and familiar word Asphyxia, which, in its etymological sense, signifies an absence of pulse (ἀ, *not;* σφύζω, *I beat*) and employ in its stead the more suitable term Apnœa (ἀ, *not;* πνέω, *I breathe*). Even the word Apnœa fails clearly to convey to the mind the true proximate cause of death; for in certain cases of suffocation animal life is extinguished, although there be no impediment to the physical part of the respiratory process, and in these circumstances it is not the absence of the respiratory act, but of the proper respiratory medium (oxygen), which determines the death of the individual. As the word apnœa is, however, applicable to the majority of cases, we prefer to retain it rather than coin a new one, which, in its turn, might be found equally inadequate to the explanation of phenomena which advancing science may afterwards reveal.

So long as animal life continues, the function of respiration knows of no intermission. By day and by night, sleeping and waking, the lungs are ever performing their allotted labor of inhaling fresh and expelling effete air.

The term "apnœa" therefore clearly defines the great truth that without respiration there is no life: man's earliest declaration of independent existence being his first respiratory effort; his seal to the abdication of life, his last expiratory act.

Few are aware how little the respiratory function is under their own control. At the first glance many might imagine that respiration is, to some extent, a semi-voluntary process, for they can temporarily arrest it at pleasure. If, however, the time men are able to cease respiring be exactly calculated, no one can fail to be astonished at its extreme brevity. Not one in a hundred can cease breathing for a single minute without suffering great discomfort; and still fewer can hold their breath for two entire minutes without yielding to an involuntary and irresistible respiratory effort. The numerous stories heard and read of persons voluntarily holding their breath for five or more minutes are simply fables. Farther on it shall even be made apparent that the numerous reports of successful cases of resuscitation after prolonged submersion—such as half an hour, for example—are pure impossibilities, originating in imperfectly observed data. Such statements would never have been promulgated had their authors for a moment considered how frequently repeated and uninterrupted the acts of respiration are. The number of respirations is alone a sufficient proof of their necessity. If, for example, the average number of respirations be taken as low as eighteen in a minute, which is somewhat under one in four seconds, it is evident that the gases essential to the continuance of organic life are renewed one thousand and eighty times in in single hour—figures which are of themselves sufficient to indicate how perilous must be even a very temporary cessation of the respiratory function. Shortly, however, other reasons will be adduced for disbelieving the statements referred to. Meanwhile it may be proper to consider the

Symptoms of Apnœa.

The first symptoms that manifest themselves when a healthy person is deprived of air are feelings of thoracic fulness and discomfort, which gradually, but rapidly, assume the form of an intense oppression. To the latter symptom is soon superadded an uncontrollable desire to breathe, which is immediately followed by violent respiratory efforts. The respiratory efforts are at first short and recur in rapid succession. They soon become deep, forcible, and prolonged, with a gradually-widening interval between them until just before they entirely cease, when they again diminish in force and duration. During this period, which, for the sake of convenience, may be termed that of respiratory movement, certain cerebral symptoms present themselves in somewhat of the following order: In the earlier part, the patient feels a sensation of fulness in the head and giddiness; experiences singing in the ears, and has flashes of light dancing before his eyes. To these, it is said by persons who have been rescued from impending suffocation, succeed pleasing, almost voluptuous, dreams, which however, soon fade away, and give place to insensibility and unconsciousness, which, in their turn, are speedily followed by convulsions and coma.

As regards the circulatory system, it is found that at first the heart's action is accelerated, partly perhaps on account of the patient's struggles for breath. This condition is but transitory; for in the space of a very few seconds its action becomes slow, labored, and feeble, till the pulse at length ceases to be perceptible at the wrist. The heart is, however, still pulsating, and the throb may be detected by the aid of the stethoscope: the action gradually becomes less and less distinct, till it entirely ceases at a period within ten minutes after the first interruption to the respiratory process. The period that elapses between the last respiratory effort and the cessation of the heart's action may be calculated to vary from two to four minutes.

The appearance of the patient during the time just described undergoes a marked change. There is an extremely anxious expression of countenance, blueness of the lips, projection of the eyeballs, distension of the vessels of the face, head, and neck, frothy mucus, occasionally sanguineous, about the mouth, and involuntary passage of urine and feces, sometimes even an emission of semen with or without erection. All of these symptoms are modified, and supervene with more or less rapidity, according to the mode in which the apnœa has been produced. Although apnœa may be induced in a great variety of different ways, each of which presents its own peculiarity, it is unnecessary at present to dwell upon the subject, the diagnosis of the case being in general attended with no difficulty, from the fact that its history clearly explains the symptoms. It has, however, happened that the medical attendant has been purposely misled into an error in diagnosis by the relatives of the patient, who, in their desire to protect the honor of the family, have occasionally not hesitated to trifle with the life of one of its members. It is therefore of importance to call attention to the danger, which a practitioner occasionally runs in such cases, of mistaking the cause of the symptoms, and thereby falling into an error in treatment. This can scarcely be more forcibly done than by briefly relating the case recorded by Mr. Thomas Stainthrope, which strikingly illustrates the truth of the remark.

On one occasion, Mr. Stainthrope was suddenly called after midnight to see a clergyman. On arrival he found the gentleman in bed, unable to speak, insensible, and presenting the symptoms of apoplexy. The relations heard the remarks of the medical attendant, listened to the line of treatment suggested, and assisted in its performance, without giving the slightest hint as to the true cause of the symptoms, or making any allusion to the fact that the patient had, a few minutes before, been found suspended by the neck to the top of his bed. Mr. Stainthrope, in the belief that the case was one of apoplexy, opened the veins of both arms, and extracted three pints of blood before any improvement in the symptoms took place. This was followed by other treatment considered applicable to the case; but it was not until ten hours had elapsed that the gentleman was able to answer questions; and no wonder, seeing that if the medical attendant had been honestly informed of the cause of his patient's symptoms, he might probably, with a little assistance to respiration by artificial means, have restored him in as many minutes. The gentleman recovered.[1]

Apnœa arising from disease may give origin to precisely the same train of symptoms as that supervening upon an accidental mechanical obstruction to the respiratory process; the only difference being that the symptoms in the former case usually progress very slowly, as for example, in cases of death from apnœa caused by œdema of the glottis; from the trachea becoming blocked up with a false membrane, as in diphtheria and croup; from the accumulation of mucus, as in bronchitis; from insufficient healthy pulmonary tissues remaining to admit of the blood becoming arterialized, as in pneumonia; and from compression of the lungs from effusion, as in double pleurisy.

In all these cases there is one remarkable circumstance observable, namely, that the lividity and congestion of the face are almost, if not quite, as apparent as in cases arising from a ligature round the neck, by which the descent of the blood through the jugular veins is interrupted. The same remark is equally applicable to cases in which the disease is external to the trachea; as, for example, in cervical tumors, aneurism, hypertrophied thymus, etc., which produce apnœa by their pressure on the trachea.

The explanation of this is simple enough. First, the face and lips are livid from the arteries conveying venous instead of arterial blood; and secondly, they are congested on account of the circulation being arrested in the lungs, which causes the right side of the heart and the large veins opening into it to be engorged; and these, in their turn, produce congestion in the vessels opening into them.

POST-MORTEM APPEARANCES.

The external appearances presented by individuals in cases of death by apnœa vary according to the manner in which it has been induced, as well as with the period that has elapsed between the examination and the extinction of life. If the examination be delayed for twelve hours, for example, the signs presented by the body differ but very slightly, if at all, from those frequently found in persons that have died from other causes. Positive evidence, indeed, can only be obtained in such cases by an internal inspection, and even that must be carefully made, otherwise the cause of the apnœa may escape detection. This remark is specially applicable to cases of accidental and intentional apnœa.

If the body is seen within three or four hours after death, its external surface will be found to present numerous discolorations. The lips are blue, and oftentimes covered with frothy mucus, which occasionally presents a slightly sanguineous appearance. It ought not to be forgotten that frothy, even sanguineous, mucus may be found about the mouth in other cases of sudden death besides that arising from apnœa. This is the case in epilepsy; in heart-disease; and on the very day of writing these lines we saw it in a marked degree in a case of concussion of the brain. The driver of a pianoforte van was thrown violently from his seat against a lamp-post; and on his being brought to University College Hospital, the slightly tinged froth around the mouth and about his nostrils was specially observed. He had been dead about fifteen or twenty minutes. The tongue is often swollen and livid, and not unfrequently shows marks of the teeth upon it. This is particularly noticeable in those cases in which convulsion has preceded death. The eyelids are half open and the pupils dilated. The countenance is generally placid, the skin of the face usually pallid, or if discolored at all, possessing a faintly livid transparency. In cases of death from drowning, the skin has now and then been observed to present the appearance denominated cutis anserina; but this is by no means a common occurrence.

---

[1] Lancet, Oct. 1, 1859.

In apnœa from the external application of mechanical means, evidences of the mode by which death has been induced generally remain visible for some hours. There may be abrasion, ecchymosis, or laceration at the injured parts. There may be the mark of a cord or of fingers upon the neck. The hyoid bone may be fractured, the cartilages of the larynx dislocated; and various other evidences of mechanical injuries, according to the manner in which the apnœa has been induced.

On the other hand, it must not be forgotten that death may arise from mechanical means, and not a trace of its nature be visible to the eye. This has frequently happened in cases of smothering and plugging of the fauces and windpipe. In such cases, therefore, the existence of the apnœa can only be detected by an internal inspection.

Even in cases of death by hanging, if the body be cut down immediately after the extinction of life, the mark of the cord or rope entirely disappears within a very few minutes, so that a person examining the body for the first time half an hour or more after death, would fail to discover any traces on the neck indicative of the manner by which life was extinguished. This arises from the fact that where there has been no excessive application of violence the mark of the cord is due (contrary to the common idea) to the post-mortem constriction; so true, indeed, is this, that if a human body be suspended by a cord immediately after death from ordinary disease, and allowed to hang for more than half an hour, the mark of the cord becomes permanently visible. These facts ought never to be forgotten, in post-mortem examinations of medico-legal import.

Moreover, the post-mortem appearances in cases of poisoning by the substances included under the head of toxic gases, vary as much as the symptoms themselves. In some they are even totally opposed. Thus, for example, while the muscular tissues and organs of an animal poisoned with sulphuretted hydrogen are of an intensely dirty-black color, those of an animal that has succumbed to the effects of pure carbonic oxide are of the most beautiful vermilion hue. So it can be readily imagined that, even if we felt inclined, it would be impossible for us, in the short space at our disposal, to give an outline of the symptoms and post-mortem appearances produced by all the substances that might be included under this heading.

As regards the much vexed question of *rigor mortis*, it may be said that it usually sets in early; and this is particularly the case after drowning in cold water, when a state of semi-freezing has been frequently observed instantly to succeed, if not actually to usher in, death. So firmly are substances occasionally grasped in the clenched hand of the drowned, that they are only to be extracted from it by the application of great force. Cases are recorded where the finger-bones have been actually fractured during the forcible opening of the hand.

Condition of the brain.—The cerebral vessels have by most authors been particularly noted as being engorged with dark venous-colored blood. Great doubts have recently been thrown on the value of this sign, however, by Ackermann, who states that from the results of experiments on animals, conducted according to Professor Donders's method of rendering visible the condition of the circulation in the brain during life, it appears that death by suffocation is always connected with an exsanguine state of the cerebral vessels; the appearances of hyperæmia, so often observed, being merely the result of the post-mortem mechanical distribution of the blood. The appearances of cerebral anæmia, the author states, are even distinguishable in cases where the animal has been strangled with a cord round its neck, and the head kept somewhat lower than its body. The anæmic condition of the brain is gradually assumed after death if the head be not kept lower than the rest of the body, and it only attains to its maximum an hour or two after death. If these assertions be correct, they clearly point to the necessity of carefully taking into consideration the position of the body after death, before drawing any conclusions from the state of the cerebral vessels.

Ackermann goes so far as to to say that the condition of cerebral anæmia is equally observable after death from compression of the chest, inhalation of chloroform, and injections of water into the lungs. The results of these experiments seem to explain why cerebral anæmia has been so frequently noted in cases of death by apnœa. It must not be forgotten that extravasations of blood under the arachnoid have been occasionally found in drowned persons. These were probably due to the injuries sustained by the head in falling from a height. Mere concussion with the surface of the water has been known to produce it; and it is common enough in persons who have come into violent contact with the bottom, or with substances floating on the water, while diving. In a case of death from the inhalation of chlorine gas, it is stated that the gas was afterwards detected in the fluid of the ventricles of the brain.

Condition of the heart and vessels.—Particular attention has been paid to the condition of the heart and great vessels in cases of death by apnœa. It is usual to find the right side of the organ, both auricle and ventricle, as well as the large vessels attached thereto, highly engorged with dark-colored blood. The left side of the heart, on the other hand, is in the majority of cases found empty; or if it contains blood, the blood is of the same venous hue as that found occupying the right side of the organ. The blood throughout the whole body, indeed, is of a similar dark tint. Some state that it presents the additional peculiarity of being fluid; but this is far from being always the case. The portal system is greatly engorged. The liver, spleen, and kidneys specially partake of the venous congestion. It may indeed be asserted, in general terms, that in death by apnœa all the internal organs are more or less engorged with dark blood. Most authors have stated that the lungs are particularly so; but although we have had our attention specially directed to this point for many years past, and enjoyed several opportunities of being present at the autopsy of persons who have perished by apnœa, we are forced to admit that this is not so invariably the case as we had been led to expect.

There being no more blood in a person killed by apnœa than in one who has died from any other cause, it is easy to see that there cannot possibly be a general engorgement of the whole vascular system. If one part of the body is particularly congested, another must be proportionally anæmic. The venous system is full of blood because the arterial is empty; and the simple reasons are—1st, that the pulsations of the heart and vessels continue after the respiration and consequent circulation in the lungs is stopped; and 2dly, the resilience of the arterial coats prevents the return of the blood into them from the capillaries. Again, as regards the congestion of the internal organs. If it be very marked, there is a corresponding pallor of the external surface. This is specially noticeable in persons drowned during the winter months, and is due to the cold causing constriction of the cutaneous vessels and driving the blood inwards.

Condition of the respiratory system.—In cases of death by hanging, strangulation, and suffocation, the lungs present no characteristic appearance; unless it be that, on opening the chest, their tissue does not collapse in the usual manner, in those exceptional cases where the exit of the air by the trachea is prevented by constriction or plugging of the windpipe. In cases of death from the inhalation of sulphuretted hydrogen gas, the pulmonary tissue is blackened, and in those from carbonic oxide gas of a fine vermilion hue.

It sometimes happens when the apnœa is due to the inhalation of toxic vapors, such as chloroform, that there are one or more small extravasations of blood found in different parts of the pulmonary tissue. Sometimes these hemorrhagic effusions are quite superficial, at others deep seated. It is more particularly in cases of death by drowning that the lungs may be said to present characteristic appearances, and to these we shall now make special allusion.

Some say that water never penetrates the lungs, in consequence of spasm of the glottis being induced as soon as the fluid comes in contact with the opening to the air-passages. Others again, with equal confidence, assert that not only water, but any foreign substance, such as mud, duck-weed, and chaff, which may accidentally chance to be floating in it, are carried into the lungs. Our personal experience, as well as that of the Royal Medical and Chirurgical Society's Committee,[1] entirely negative the former, and support the latter, statement.

Into the lungs of every animal, without a single exception, experimented upon by the committee, the fluid in which the animal was immersed freely entered. The extraordinary force by which substances are drawn into the lungs in cases of drowning was estimated by the committee, and found to be equal to the raising of a column of mercury four inches.[2] When dogs were drowned in plaster-of-Paris, on examining the lungs after death the white plaster could easily be detected in the minute bronchial tubes. Even in the lungs of guinea-pigs held upside down, with only the nose immersed sufficiently deep in mercury to prevent the possibility of the animal getting any air, globules of the metal were readily detected in the minute tubes, thereby proving that this weak animal's respiratory efforts were capable of drawing the mercury the distance of one or two inches in spite of gravitation. The lungs of animals drowned in pure water, when examined immediately after death, were found by the committee to be saturated and sodden with water to such an extent that they pitted on pressure, felt doughy to the touch, were exceedingly heavy, and incapable of collapsing. The air-tubes were choked up with a sanious foam, which consisted of blood, water, and mucus, churned up with the air in the lungs by the respiratory efforts of the drowning animal. On section of the pulmonary tissue, frothy water stained with blood poured out at every point.

---

[1] As it will frequently be necessary, in the course of this article, to refer to the results obtained by the committee, it may, perhaps, be as well to mention that the gentlemen composing it were: C. J. B. Williams, W. S. Kirkes, George Harley, J. B. Sanderson, C. E. Brown-Séquard, H. Hyde Salter, W. S. Savory, and E. H. Sieveking, Hon. Sec. Med.-Chir. Soc. (ex-officio). The report appeared in the forty-fifth volume of the Society's Transactions, 1862.

[2] Vide report, Med.-Chir. Trans., vol. xlv., p. 455.

How can this fact be reconciled with the statement so often made, that no water is to be found in the human lungs after death by drowning? We have ourselves failed to detect water in the respiratory organs of a young woman, aged 23, who committed suicide by drowning. The lungs, when examined twenty-four hours after death, crepitated readily on pressure, except in the most depending portions, to which the blood and water, if there was any, had gravitated. The failure in detecting water in this case, however, did not excite the least surprise, notwithstanding our being in possession of the above-mentioned data; for we were at the same time acquainted with the important fact of the powerful absorbing power of the pulmonary tissue. It is almost impossible to say how much water may be taken into, and disappear by absorption from, the lungs during the act of drowning. It must be remembered that the extinction of life in cases of submersion is not due to water entering the lungs, but solely to the absence of air. If air be allowed to enter the lungs at the same time as the water, the animal suffers little or no inconvenience from the presence of the latter in the pulmonary tissue. One can wash out the lungs by a continuous stream of water, and the animal yet live. It may even be all the better for the species of pulmonary irrigation. It is only during the first few minutes that water induces much irritation, and causes the animal to struggle and cough. The irritation soon subsides; and if the water is allowed steadily and slowly to flow into the lungs, no apparent inconvenience arises. Even half-an-ounce may be suddenly thrown into them, and, after causing the animal to make one or two deep inspirations, entirely disappear. This may be repeated at intervals of a few seconds for at least half an hour, without in the slightest degree endangering life. All that is required to ensure success in this experiment is simply to allow of the admission of a sufficient quantity of air to keep up the arterialization of the blood.

We have inserted and firmly tied into the trachea of a large dog a long glass tube, to the upper end of which a glass funnel was attached, in order to enable the experimenter the more easily to pour in water; and while the animal was lying on its back, ounce after ounce of water has been thus introduced into the lungs, and from thence absorbed into its circulation, without producing any visible disturbance, except during the few seconds that the water in its transit blocked up the tube and prevented the entrance of air.

If water be, as has been already said, slowly poured into the lungs, and sufficient air at the same time admitted, thirty, forty, or fifty ounces may be easily introduced in as many minutes; and on killing the animal an hour or two afterwards, not a trace of the liquid be found in the pulmonary tissue; the lungs at the same time appearing none the worse for the experiment.

There cannot be any longer much question about water entering the lungs in cases of drowning; and its absence in post-mortem examination is due, in all probability, to its subsequent absorption. In cases of persons drowned in ponds, duck-weed and other matters floating on the water have frequently been found in the trachea and bronchi, and yet no liquid detected in the pulmonary tissue. We have observed that in an animal that has struggled much, and frequently got its nose to the surface for a sufficient length of time to inhale a little air, there is far less water found in the lungs than in one that has been from the first wholly submerged. This is precisely what happens with human beings, who, even in cases of suicide, generally struggle for some time, and thus succeed in obtaining occasional gasps of air, at last succumbing to the combined effects of exhaustion and suffocation. Again, it may happen that on removal from the water the body may be so placed as to admit of the exit of any fluid that may chance to be present in the trachea and lungs. These are points which will be more easily understood after having discussed the pathology of drowning, so that it will be better in the meanwhile to turn attention to the consideration of the

Physiology and Pathology of Apnœa.

In order to be philosophical as well as practical in the exposition of the physiology and pathology of this mode of death, it will be necessary to divide the various forms of death by apnœa into the four following classes, the subdivisions of which, for the sake of brevity, are best put in the shape of a skeleton diagram :—

Apnœa, 1st, from a mechanical impediment to the entrance of air into the lungs.

2d. From drowning.

3d. From the absence of oxygen in the respired gas.

4th. From the inhalation of a toxic vapor associated with an absence of oxygen.

Apnœa may arise from

- 1st, Mechanical impediment to the entrance of air into the lungs.
  - Accident.
    - External.
      - Pressure on the trunk preventing the expansion of the chest; throttling; garrotting; strangulation by a cord; hanging; smothering by covering the mouth and nostrils, imbedding the face in earth, feathers, wool, etc.; paralysis of the respiratory muscles from injury to the spinal cord, or to the base of the brain; or a double penetrating wound of the chest admitting air.
    - Internal.
      - Choking from a morsel of food or other substance blocking up the fauces; plugging of the trachea by a cherry-stone or other substance; constriction of the fauces and injury to the glottis from application of corrosive and irritating fluids.
  - Disease.
    - External.
      - Pressure on the trachea from an aneurism or other tumor.
    - Internal.
      - Œdema of the glottis; tumor on or about the vocal cords; false membrane blocking up the air-passages, as in diphtheria and croup; bursting of an abscess or aneurism into the trachea; double pneumonia or pleurisy; accumulation of mucus in the bronchial tubes; apoplexy at the base of the brain or in the medulla oblongata, causing paralysis of the pneumogastric nerve and of the respiratory muscles.
- 2d, Drowning . . . . . .
  - In any liquid of whatever nature —water, wine, beer, or brine.
- 3d, Absence of oxygen in the respired gases.
  - Inhalation of pure nitrogen, hydrogen, or any other innocuous gas.
- 4th, Inhalation of a toxic gas or vapor.
  - In which death is erroneously attributed to apnœa.
    - Carbonic acid, carbonic oxide, coal-gas, choke-damp, ammonia, chlorine, sulphuretted hydrogen, arseniuretted hydrogen, antimoniuretted hydrogen, sulphurous acid, nitrous acid, hydrocyanic acid, vapor of chloroform, ether, amylene, or any other volatile product.

Death from a mechanical impediment to the entrance of air into the lungs.—In many of the examples of death by apnœa cited in the above table, it is evident that it must occasionally happen that the death is accelerated by the direct action upon the body of the cause producing the apnœa. Thus, even in the first sub-class, which is specified as being due to mechanical obstruction to the entrance of air into the lungs, it can readily be imagined that the patient does not always succumb from pure apnœa. Fracture of the ribs, rupture of the liver, and many other injuries, may arise from pressure on the trunk, and thereby tend greatly to accelerate death. But there can be no doubt that in the majority of cases of suffocation arising from pressure on the thorax and abdomen preventing the expansion of the chest and consequent inhalation of air, apnœa is the immediate cause of death. For example, it would have been so in the case of the black athlete, who nearly lost his life in consequence of the shrinking of the plaster of Paris in which he was enveloped while having a cast of his body taken. The plaster shrank as soon as it began to set, and compressed the chest to such an extent that the poor man could neither breathe nor speak, and the extreme danger of his situation was only discovered just in time to rescue him from impending suffocation. In this case death would have been the result of apnœa.

Persons crushed in a crowd may die, in the same way, of pure apnœa, and even these accidentally buried beneath a fall of earth or stones, as well as such as are strangled with a cord, garrotted with the arm, or throttled with the hand; but in no one of these cases is pure apnœa of necessity the only cause of death. As a striking illustration, let us take death by hanging. It is known that, as a rule, the person is suffocated by the pressure of the rope on the trachea preventing the admission of air into the lungs. Occasionally it happens, however, especially in hanging at legal executions, where the body is allowed to fall from a distance with a sudden jerk, that the death is instantaneous, in consequence of dislocation or fracture of the vertebræ, with an accompanying lesion of the spinal cord. The contrary may likewise occur, and instead of death being more rapid, it may in reality be slower than in pure apnœa. This may arise from the position of the rope on the neck being such as to interfere with the circulation in the jugular veins, and thereby induce an artificial apoplexy, which, by reducing the necessity for oxygen, allows the life of the individual to be prolonged beyond the limit allotted to pure apnœa. This statement will be readily appreciated after the effects of anæsthesia in cases of drowning have been explained.

It is hence evident that if we wish to study the phenomena presented in cases of death by pure apnœa, arising from a mechanical impediment to the entrance of air into the lungs, and to recognize the order of their sequence, it will be necessary to turn our attention for a few minutes to its least complicated form; and this unfortunately can only be satisfactorily illustrated by reference to experiments on animals. We must therefore leave aside, for a time, the consideration of its effects upon the human being.

The Committee of the Royal Medical and Chirurgical Society has furnished the following important data:—

First, the duration of the respiratory movements.

Secondly, the duration of the heart's action.

Thirdly, the duration of the heart's action in relation to the duration of the respiratory movements.

The method of experimenting was as follows: The animal was secured on its back, and the trachea exposed by a single incision in the mesial line of the neck. A ligature having been passed round the windpipe, it was opened by a vertical cut, and a glass tube, as large as could be conveniently inserted, was passed into it for a short distance downwards, and firmy secured by the ligature. Through this tube, while patent, the animal breathed freely, but the supply of air could be at once completely cut off by inserting a tightly-fitting cork into the upper end of the tube. It was ascertained by separate experiments that the tube thus plugged with the cork was perfectly air-tight. From the result of nine experiments performed in this manner it was found—

First, that in the dog the average duration of the respiratory movements after the animal has been deprived of air is four minutes five seconds; the extremes being three minutes thirty seconds, and four minutes forty seconds.

Secondly, the average duration of the heart's action is seven minutes eleven seconds; the extremes being six minutes forty seconds, and seven minutes forty-five seconds.

Thirdly, the results of the experiments led to the belief that, on an average, the heart's action continues for three minutes fifteen seconds after the animal has ceased to make respiratory efforts; the extremes being two and four minutes respectively.

In the case of three domestic rabbits experimented upon, it was found that, on an average, they ceased to make respiratory efforts in three minutes twenty-five seconds; that their hearts' action stopped in seven minutes ten seconds; and consequently that the interval between the last respiratory effort and the cessation of the heart's action was three minutes forty-five seconds.

It will be here observed that there is no very marked difference either between the duration of the respiratory movements or of the heart's action in the powerfully-constituted dog and the weakly-constituted domestic rabbit. It appears, therefore, that in the absence of any positive reliable data regarding the absolute duration of the respiratory movements and of the heart's action in man in cases of death by uncomplicated apnœa, one may venture to assume that they do not differ very materially from those of the animals just cited.

The next point of importance to ascertain is the latest period at which recovery is possible after the simple deprivation of air. Here again the committee has furnished important data, which may be usefully turned to account in considering the subject of treatment in the case of the human being.

The result of the experiments led to the conclusion—1st, that a dog may be deprived of air during a period of three minutes fifty seconds, and afterwards recover without the application of artificial means; and 2dly, that a dog is not likely to recover if left to itself after having been deprived of air during a period of four minutes ten seconds. Other experiments tended also to confirm the above fact, viz., that in dogs the doubtful interval of recovery and death lies between three minutes fifty seconds, and four minutes ten seconds.

From the results obtained by the committee while engaged in ascertaining the exact period after the simple deprivation of air at which recovery is possible under natural circumstances without the aid of any artificial means of resuscitation, it was found possible to deduce the following conclusions, which most probably are as applicable to man as to the animals experimented upon by the committee.

1st. That a state of apnœa being maintained for a given time, the later the respiratory efforts are continued, *i. e.*, the shorter the interval between the last respiratory effort and the admission of air, the greater the chance of recovery.

2d. That air being admitted at a given time after the last respiratory effort, the earlier the respiratory efforts cease the greater the chance of recovery; for the earlier they cease, the shorter the interval between the establishment of, and the release from, the state of apnœa.

3d. In respect to the relation between recovery and the duration of the heart's action, it was found that under no circumstance did recovery ever occur when the heart's action, as indicated by a needle[1] inserted into the organ, had stopped.

Apnœa from submersion.—We have now to consider the second form of death by apnœa, viz., that by drowning. As will be immediately seen, it presents conditions differing widely from those met with in any of the forms of death just considered, arising from the mechanical obstruction to the entrance of air into the lungs.

First, as regards the length of time a person may be submerged and yet recover.

Before discussing this point in connection with the human being, it will be advisable, in order to place the subject in its clearest light, first to examine the results which have been obtained from experiments on animals, as they explain many of the phenomena occurring in man which have hitherto been regarded as obscure.

Having seen what the effects of simple apnœa are, we shall now proceed to quote the results of the experiments performed by the committee, which illustrate the effect of drowning.

1st. When a dog was kept under water only one minute, it recovered.

2d. When a dog was submerged one minute fifteen seconds, it also recovered.

3d. When a dog, treated precisely in the same manner, was submerged one minute thirty seconds, it died; and this was invariably the case, even when the animal was not only able to make spontaneous efforts at respiration, but actually capable of giving a cry after its removal from the water.

Thus, then, we are here furnished with the remarkable fact, that whereas in simple apnœa recovery is always possible after three minutes fifty seconds, only one and a half minute's complete submersion in water suffices to destroy life. To what is this extraordinary difference due?

In order to solve this question the committee placed two dogs under precisely similar circumstances, with the exception that in the one case the free access of water to the lungs was permitted, and in the other prevented. The following were the experiments:—

First. Two dogs of the same size were fastened to the same plank and submerged at the same moment, one of them having previously had its windpipe plugged in the usual way, and the other not. At the end of two minutes they were simultaneously removed from the water. The one that had the trachea plugged at once recovered; the other died.

Secondly. The above experiment was repeated, the dogs being kept under water four minutes. When removed from the water, the dog that had his trachea plugged got up in a few minutes comparatively well; while the other, though gasping when taken out, died.

---

[1] The duration of the heart's action was conveniently ascertained by means of a long pin inserted through the thoracic walls into some part of the ventricles. So long as the heart continued to beat the pin moved, and its motions were thus recorded for some time after the cardiac sounds had ceased to be audible. The needle may be withdrawn and reinserted several times without producing any other result than slight temporary acceleration of the heart's action.

These experiments satisfactorily show that the difference between apnœa produced by plugging and that by drowning is not due to submersion, to depression of temperature, or to struggles, seeing that the two animals were placed under precisely similar conditions, with this most important exception, that in the one case a free passage of air out of the lungs, and of water into them, was permitted; in the other, the exit of air and the entrance of water were alike prevented.

There can be no doubt that both these circumstances are concerned in producing the difference in the results of the two experiments. Moreover, the condition of the lungs, as revealed by post-mortem examination, appeared to the committee to furnish a further proof that the shortness of the period of immersion, which proves necessarily fatal to an animal, is mainly due to the entrance of water, and the effects thereby produced.

On examining the lungs of the animals deprived of air by plugging the trachea, they were found simply congested; but in the animals drowned, not only was the congestion more intense, accompanied with ecchymosed points on the surface and in the substance of the lung, but the air-tubes were completely choked up with a sanious foam, consisting of blood, water, and mucus, churned up with the air in the lungs by the respiratory efforts of the animal. The lung-substance too was heavy, and saturated with water.

Since the conclusion of the labors of the committee, we have carried the inquiry a step further, and ascertained that the effects of the water extend beyond the mere pulmonary tissue. In some carefully-performed experiments, we found that in cases of drowning the blood in the left side of the heart contains much more water than that on the right; and when examined microscopically, the blood-corpuscles from the two sides of the heart present entirely different appearances. Thus, for example, we ascertained that while in the blood of the right auricle or ventricle the corpuscles may be nearly all serrated, in the watery blood from the left side of the organ it is not only frequently utterly impossible to detect a single serrated corpuscle, but in the latter blood, many of the cells have swollen up, burst, and allowed their coloring matter to escape, and stain the serum of a deep red color. In some cases we also noticed that occasionally, when there was scarcely a whole blood-corpuscle to be seen, the field of the microscope was occupied by an immense number of small bodies like escaped nuclei, and we are not yet quite certain that they were not nuclei, notwithstanding it was dog's blood we were examining, which is supposed to possess only non-nucleated blood-corpuscles. Although this peculiar effect of the water on the blood-corpuscles may have something to do, as we shall presently see, with secondary apnœa, we do not consider that it influences, to any marked degree, the rapid extinction of life in cases of complete submersion. The death in such cases is much too speedy to be thus accounted for. We shall shortly see that the difference in the time required to drown and to suffocate an animal must be due to an entirely different element, namely, the presence or absence of air in the lungs. That a moderate amount of air suffices to sustain life for some length of time is well illustrated, as regards the human being, in the case of sponge- and pearl-divers, who, through the influence of habit, are able to bear submersion for a period which would be exceedingly perilous to the non-habituated. Lefevre states that he has seen Navarino sponge-divers remain under water for nearly two minutes, their average time of submersion being about eighty seconds. Mr. Reynaldo, late Port-surgeon at Bombay, informs us that he has frequently timed the most expert divers in the Bombay harbor, and that some of them could sustain entire submersion for two and a half minutes. In order to accomplish this, however, they are forced to employ an artificial aid to the retention of the air in the chest. Immediately before diving they forcibly distend the lungs with air, and instantly afterwards slip over the nose a clip made of a bullock's horn, in order to prevent any involuntary expirations. The lips, being much more easily controlled than the nostrils, are left unprotected.

For the reasons given at pp. 91, 92, when treating in general terms of the effects of the introduction of water into the lungs, it cannot be said that the greater rapidity of death in submersion over simple apnœa depends on the deleterious action of the inspired water; and, as has just been shown, it is equally impossible to attribute it either to the struggling of the animal or to the external influence of the water on the frame. One is thus compelled to seek for another explanation of the phenomenon. It appears to our mind that the true explanation lies in the facts just alluded to, namely, that when the lungs are full of air, the escape of which is prevented, the animal obtains sufficient oxygen to support life for at least double the time it would do if they were entirely empty. Thus, for example, when the trachea of the animal is plugged, as in the experiments of the committee, not only is the entrance of water prevented, but the exit of air is stopped. So also in the case of the pearl divers: the clip on the nostrils acts the part of the plug in the trachea, and, by putting a restraint on involuntary respiration, enables the individual to retain in the lungs a quantity of air from which the blood can extract sufficient oxygen to prolong life within certain limits.

Dr. Sanderson, moreover, informs us that he has been able to demonstrate this fact by direct experiment, and that he finds that in animals the duration of life, up to a certain point, is in an exact ratio to the quantity of air confined in the chest.

When an animal is entirely submerged and fills its lungs with water, all, or nearly all, the air contained in the pulmonary vesicles at the moment of its submersion is expelled, and it is thereby placed in the most unfavorable circumstances for the prolongation of its life. The same thing occurs when an animal is confined in a jar of pure nitrogen gas. The air in the lungs is rapidly replaced by a gas incapable of supporting life, and the animal speedily perishes—much sooner than if the lungs were filled with air and the trachea plugged. These facts, as we shall presently find, are of the utmost value in connection with the subject of treatment; for, as will be seen, paradoxical as it may appear, the best way to preserve life, under certain circumstances, is to stop breathing.

Effects of syncope in cases of drowning.—The occurrence of syncope is said greatly to augment the chances of recovery in cases of submersion. And it does so, no doubt, within certain limits, for the same reason as anæsthesia does, namely, by reducing the number of respirations. It has, however, a still further advantage in temporarily arresting tissue-metamorphosis, and thereby reducing the necessity for oxygen. We cannot, however, believe that syncope is capable of prolonging life beyond a very few minutes, for the simple reason that the heart's action cannot be arrested for even a very brief space of time without inducing a fatal result. In a drowned animal, although the movements of respiration stop much sooner, half as soon again as in a strangled one, the heart's action continues for nearly the same length of time, namely, from seven to nine minutes; and in neither case is it possible to resuscitate the animal after the entire cessation of the heart's action.

It appears to us that the majority of persons have most erroneous notions regarding the duration of syncope in general, and syncope under water in particular. Many cases, where the patient is not submerged, are mistaken for syncope, which are not in reality such; both the respiration and the heart's action continuing, but so feebly as, in a cursory examination, to escape detection. We doubt very much, judging from what we know of the phenomena of the cardiac action (for, be it remembered, there is no direct evidence one way or another), if it is probable, or even possible, for the heart to resume its action after five minutes' entire cessation. This leads to the question, *How long may a human being be under water, and yet recover?* This entirely depends on the degree of the submersion. If a person be completely submerged, and the entrance of water to, and exit of air from, the lungs not prevented, we believe that recovery would be impossible after two minutes. On the other hand, if the air-passages were closed against the entrance of water, and the chest kept full of air, we see no reason for thinking that a human being would perish either more slowly, or more quickly, than a dog placed under similar circumstances—namely, in from four to five minutes.

The reason why some persons remain a long time in the water, and yet ultimately recover, is that they are never, or at least only for a very short part of the time, totally deprived of air. Every now and then their heads come to the surface, and they obtain an inspiration. Even if they can but gasp in a small quantity of air, and that too accompanied with water, they may be able to struggle on for a long time, as it is only the total deprivation of air that kills quickly. A person can exist for an hour on a very small quantity of air, if it be but frequently enough exchanged. This fact we see illustrated every day in the persons of patients suffering from pneumonia supervening on phthisis, who struggle on for hours with only a portion of their lungs capable of performing the functions of respiration. Then, again, as regards the damage done to the pulmonary tissue by the entrance of water, that, we have already seen, can at most be but very trifling, for the liquid is rapidly absorbed into the circulation from the pulmonary vesicles, and leaves scarcely a trace of its transit (see p. 91).

The effect of water upon the blood itself is much more marked; for, as was said at pp. 95, 96, it thins the vital fluid, and when in large quantity even destroys a number of the blood-corpuscles. When we consider, however, the very large amount of blood in an adult body, at least fifteen pounds, and the proportionally small amount of water taken in at a time, we can readily understand how it is that its effects are rendered apparent only in cases of complete submersion. In the case of dogs whose lungs have been irrigated with water, it is difficult to detect any deleterious action of the water upon the blood-corpuscles; and this probably arises from its rapid elimination preventing any visible injurious dilution of the vital fluid. Such an action it must, however, to some degree exert.

The effect of temperature on the rapidity of death in cases of drowning.—The temperature of the water influences to some extent the rapidity of the fatal result. If we take the normal temperature of the animal as the starting point, we find that death is more rapid as we descend towards the freezing, and ascend towards the boiling point. The temperature of the human body being, in round numbers, 100° F., if a person be submerged in water at the freezing point, *cæteris paribus*, the quicker is the death. This conclusion we have arrived at from the results of experiments on animals, as well as from what we witnessed in the human being a few years ago, when fourteen persons were nearly drowned by the sudden breaking-up of the ice on the water in the Regent's Park. The explanation appears simple enough, when we remember that intense cold paralyzes the muscular energies of the individual, and thereby prevents his continuing the efforts requisite to enable him to get occasional inspirations; consequently the person becomes totally submerged more quickly than he would otherwise be.

Heated water, on the other hand, seems to favor death by hastening the action of the already weakened heart, as well as by accelerating tissue-metamorphosis, and thereby increasing the demand for oxygen.

It is only when water is considerably below or above 100° F. that the effects of temperature become visible; a degree or two one way or the other gives rise to no apparent effect.

Apnœa the result of an absence of oxygen in the respired medium.—The simplest form of death arising from apnœa, or the non-arterialization of the blood, is when there is no obstruction to the entrance of air into the lungs, but merely an absence of oxygen in the inspired gas. This is well illustrated, for example, when an animal is placed in a jar of nitrogen. It dies, and that too in a very few minutes; not from the introduction of a poisonous material into the system, but solely on account of the absence of oxygen in the inspired medium.

Nitrogen is perfectly harmless to animal life. We are constantly breathing it, and suffer no disagreeable effects from it. On the contrary, it is a necessary diluent of the oxygen of the air. The atmosphere normally contains no less than 79 per cent. of it. Nitrogen itself is, however, neither a supporter of combustion nor of life; hence it is that animals cannot live in it. Moreover, they die quicker in perfectly pure nitrogen than when strangled, for the reason previously given, namely, that the inhaled nitrogen displaces a certain amount of the oxygen from the air-vesicles, and thereby reduces the animal to the condition of one whose air-vesicles have been emptied of oxygen by water. The influence of nitrogen extends even somewhat further. For, according to Graham's law of the diffusion, and Henry and Dalton's law of the absorption, of gases, the inspired nitrogen not only displaces the free oxygen present in the pulmonary air-vesicles, but withdraws the absorbed oxygen from the blood itself. This is probably the true explanation of the fact that animals die more rapidly when placed in perfectly pure nitrogen gas than when suffocated in any other way. Hydrogen acts in a nearly similar manner; but its effects on the animal body have not been sufficiently studied to admit of our drawing any general conclusions from them. Some have even hinted that hydrogen gas has special toxic properties; if so, it ought, properly speaking, to come under the next head.

Apnœa from the inhalation of toxic gases and vapors.—There are very few gases that cause death by true apnœa. Most, indeed all, with the exception of nitrogen and hydrogen, and possibly even the latter, as has just been said, kill by means of their toxic properties. Although, therefore, we have been compelled on this occasion to sacrifice scientific accuracy to common custom, and include under the headings of death by apnœa that arising from the introduction into the system of noxious gases and vapors from volatile liquids, we shall merely point out how their action is totally distinct from that of pure apnœa, and then pass on to another department of our subject.

In the case of the inhalation of each of the gases included under this head (see table at p. 93), carbonic acid, carbonic oxide, charcoal vapor, coal-gas, sulphuretted hydrogen, arseniuretted hydrogen, chlorine, sulphuric ether, chloroform vapor, etc., there may be, no doubt, an absence of oxygen in the respired medium; but in no one of these cases can this be regarded as the sole cause of the fatal result. Quite the contrary; it appears rather that the destruction of animal life in the majority, if not in all these cases, depends much more upon the entrance of the toxic agent into the circulation, than upon the mere deprivation of oxygen. Consequently the symptoms manifested in cases of poisoning by these gases differ according to their chemical nature, and the intensity of their poisonous properties. Let us take arseniuretted hydrogen, for instance; if this gas be so given as to exclude the simultaneous introduction of oxygen, the animal dies not only much quicker than it does when its windpipe is tied, but also quicker than when it is suffocated in pure nitrogen gas; the cause of the difference in the rapidity of action being simply due to the toxic effects of the gas upon the nervous system. With chloroform the fact is equally well exemplified. Death from chloroform is commonly placed among the deaths from suffocation. Now, the results of the experiments of the Chloroform Committee of the Royal Medical and Chirurgical Society (1864) have shown that a chloroform death is not one by apnœa at all, but is unmistakably one by pure asthenia. When the undiluted vapor of chloroform is introduced into the lungs, animal life is rapidly destroyed, much more rapidly, indeed, than under the very quickest form of death by apnœa. Thus, while a drowned dog makes attempts at respiration during at least two minutes, and its heart's action continues to be perceptible for seven minutes, a dog poisoned with undiluted chloroform vapor inevitably dies in fifteen seconds; both respiration and cardiac pulsation being totally annihilated in that brief space of time. These are fortunately not the usual effects of chloroform; for since it is generally given in a diluted state, the oxygen of the atmospheric air with which it is accompanied suffices to arterialize the blood sufficiently for the maintenance of organic life. But even death arising from diluted chloroform vapor is in no case due to apnœa, but to the poisonous nature of the substance itself. This is proved by the cessation of the heart's action occurring almost as soon as efforts at respiration cease, as well as by the blood on the right side of the heart being darker than on the left, neither of which is ever the case in apnœa; the heart in apnœa always continuing to beat two or three minutes after the respiration has stopped, and the color of the blood on both sides being invariably identical.

Even carbonic acid circulating in the capillaries acts as a direct poison on the tissues. This we have seen well illustrated while studying the duration of the cardiac pulsations after different modes of death. Thus, the heart of a cat that has been suddenly deprived of life by section of the spinal cord at the vital point, will continue to pulsate, under favorable circumstances, for forty minutes after the animal's death; whereas the heart of a cat allowed to die slowly by strangulation, under the same circumstances, generally stops in less than twenty minutes after the death of the animal.

Enough, we think, has been said to show that these gases and vapors are in reality active poisons; and perhaps also sufficient to convince our readers that, notwithstanding the extreme interest of the subject, it would be injudicious for us to give to it more prominence in an essay on apnœa.

THEORY OF THE CAUSE OF DEATH IN APNŒA.

Various authors in explaining, or attempting to explain, the reason of the cessation of the vital functions in cases of death by apnœa, have given very different views of the subject. One ascribes the death to a mechanical stagnation of the blood in the lungs (Haller's original doctrine). Another thinks it due to the non-stimulating venous blood failing to excite the heart's action (Goodwyn). A third, to the poisonous effects of venous blood upon the tissues (Bichat). A fourth, to the gradual failing of the blood to penetrate the pulmonary tissue (Alison). While, lastly, the doctrine which has now received almost universal assent is that first propounded by Kay, namely, that the cause of death in apnœa is due to the circumstance of the capillaries of the lungs, which usually convey arterial, being incapable of conveying venous blood; and consequently that the blood, as Haller said, stagnates in the lungs. Moreover, that the functions of the muscular organs, the heart included, gradually cease on account of this arrest of the pulmonary circulation, and not, as Bichat imagined, because of venous blood possessing any noxious quality.

It is thus seen that, in Kay's doctrine, although it is doubtless admitted that in death by apnœa the heart's action is weakened in consequence of the imperfect stimulus afforded to it by the venous blood penetrating its substance, the main cause of the failure of the circulation is supposed to be the difficulty which the non-arterialized blood finds in passing through the capillaries of the lungs.[1] This theory was thought consistent with all the phenomena observed in cases of death from apnœa. It will be found, however, from what has preceded, that in the explanation of apnœa, as now understood, this theory is open to objections. Indeed, the same observation is applicable to all the theories that have as yet been advanced; for the particular reason, that they one and all, with the exception of Goodwyn's, have for their foundation that part of the original doctrine of Haller which attributes the failure of the heart's power and loss of nerve-function to the arrest of the pulmonary capillary circulation.

---

[1] Vide Watson's Lectures on the Practice of Medicine, 3d ed., vol. i., p. 69.

The result's of Goodwyn's experiments, had they been properly considered, might have led to a different conclusion from the above; for in them it is clearly shown that, for a time at least, the non-arterialized blood passes through the lungs, and enters the left auricle and ventricle of the heart. Moreover, in apnœa it is the right side of the organ that first ceases to pulsate. Bichat appears to have had a clearer idea of the sequence of death in apnœa than any previous or subsequent writer, and may be said to have only failed in arriving at the truth from having held to the idea that venous blood poisons the tissues with which it is brought in contact.

In attempting to explain the cause of death by apnœa, it is necessary to go a step or two farther than has hitherto been done; and, instead of merely limiting the question to an explanation of the most prominent of the effects of this mode of death, to attempt to follow up the subject until we arrive at the proemial cause of the arrest of the various functions. In order to do this it is necessary to begin ab initio.

As is well known, the continual afflux of arterialized blood to the various animal tissues is a condition not only important but imperative to the continuance of life. All the molecular transformations of organized matter, of which "life" is but the manifestation, are so utterly dependent on the continued supply of scarlet blood, than no sooner is it cut off than they instantly cease. Without oxygen there can be no life. Not a single new cell can be formed, not a single old one can be destroyed, without the influence of this all-important agent. From the first moment the animal germ springs into existence, during its development into tissues, and throughout its whole life as an organized body, up to the time of its death, arterialized blood is being uninterruptedly employed; and in exact proportion to its supply, cæteris paribus, are the many and intricate organic functions accelerated or retarded. Nervous action, muscular contraction, secretion, and excretion, are all equally under its sway; so that it is impossible to feel in the least degree astonished that in apnœa, which essentially consists in the arrest of the oxygenization of the blood, all the functions of life should be rapidly brought to a standstill.

Apnœa may with perfect justice be defined as death from arrested interstitial nutrition.

Were it considered necessary to prove the basis on which this doctrine rests, there would be no difficulty in so doing; for all that is required is simply to draw a parallel between the effects of a deficient supply and an impaired quality of nutritive material on the various functions of the body, when it will be immediately seen that their effects are in reality identical. For example, we have a striking illustration of the effects produced on the body by a sudden deficiency in the supply of blood presented to us in cases of death by hemorrhage. In these cases there is of course an actual absence of nutritive materials; and, as will presently appear, that absence gives rise to precisely the same chain of symptoms as is met with in pure apnœa; which, on the other hand, is an apt illustration of the effects of an impaired quality of the material.

Thus, in death by hemorrhage, there are the confusion of ideas, the unconsciousness, the convulsions, the stupor, the paralysis of the muscles, the stoppage of respiration, and, lastly, the cessation of the heart's action; all following upon each other in precisely the same order of sequence, and with the same ultimate result, as in those cases where there is no absence of the material themselves, but only of that substance which fits them for the performance of their peculiar office—oxygen.

The same thing even occurs, when not only the materials but also the oxygen itself is present, if the two are prevented from combining, and thereby becoming fitted for the purposes of nutrition. This occurs, for example, when there is present in the circulation a foreign material which possesses the property of preventing the constituents of the blood from entering into combination with oxygen. In such a case precisely the same symptoms may be induced as we have seen follow either the entire absence of both nutritive materials and of oxygen, as in hemorrhage; or only an absence of oxygen, as in apnœa. Alcohol might be cited as an example of a substance possessing the power above alluded to; and the symptoms it gives rise to, when taken in a poisonous dose, closely resemble in many respects the effects of slowly-induced apnœa. The peculiar effect which alcohol exerts in preventing the oxidation of the constituents of the blood has been illustrated by us in the following manner:—

A certain amount of cow's blood was confined with an equal quantity of pure atmospheric air, and kept at a moderate temperature during twenty-four hours. At the expiration of that period the air was found to have undergone a change: it had lost oxygen and gained carbonic acid.

For while the pure atmospheric air brought in contact with the blood consisted of

Oxygen . . .	20.960	total 20.962
Carbonic acid .	0.002	
Nitrogen . . .	79.038	
	100.000	

that removed from the retort after its twenty-four hours' contact with the blood consisted of

Oxygen . . .	10.58	total 14.9
Carbonic acid .	3.33	
Nitrogen . . .	86.09	
	100.00	

thereby showing that oxygen had been absorbed, and carbonic acid exhaled. To a precisely similar quantity of blood from the same animal was added 5 per cent. of alcohol. The blood was then placed in contact with an equal amount of pure atmospheric air, and kept twenty-four hours at the same temperature and under precisely the same circumstances as the others; notwithstanding which the air on analysis was not found to have become nearly so much changed as in the second case when it was in contact with pure blood. On the contrary, the air was found on analysis to consist of

Oxygen . . .	16.59	total 18.97
Carbonic acid .	2.38	
Nitrogen . . .	81.03	
	100.00	

proving that alcohol possesses to some extent the power of arresting the arterialization of the blood, and thereby its becoming fitted for the purposes of nutrition.[1]

The effects of alcohol and many other substances on the nervous system are, in a great measure, due to their action on the blood; and, if the above explanation be the correct one, there can be no difficulty in understanding why, in certain cases of poisoning, the symptoms so frequently resemble in some respects those met with in pure apnœa.

As a further illustration of the intimate connection between functional activity and oxidation, we might call attention to what is observed to occur during muscular contraction.

It is a well-known fact that the exposed muscles of the frog absorb oxygen and exhale carbonic acid in definite proportion, so long as muscular irritability continues; and that as soon as the irritability of the muscles ceases, an important difference occurs in the amount of the gases interchanged. Moreover, we have found that anything that interrupts the interchange of the gases tends to arrest the muscular action. This is best seen in connection with the rhythmical action of the involuntary muscles of the heart when it has been separated as far as possible from all nerve-influence. As is well known, the extirpated heart of a healthy frog will continue to pulsate regularly for an hour after its separation from the nerve-centres; we have, however, observed that if the heart be placed in contact with any of those substances that possess the power of preventing the arterialization of the blood, its action is speedily arrested. In illustration of this we may cite the following experiment which we performed several years ago (Lancet, 14th June, 1856).

When the hearts of two frogs are removed from the body, and one placed in pure distilled water, while the other is put into a solution of the acetate of strychnia (strychnia has the power alluded to, of preventing the absorption of oxygen and exhalation of carbonic acid by the blood), the former will pulsate regularly for more than an hour, the latter will cease to beat in from *one* to *five minutes*, according to the strength of the solution of the poison. And what is still more remarkable, the contractile power of the heart is gone forever. Mechanical, chemical, or galvanic stimuli alike fail to reawaken it.

(Since the foregoing was written, we have had occasion, in the capacity of member of the Royal Medical and Chirurgical Society's Chloroform Committee, to study the effects of the direct action of the vapor of chloroform and ether upon the heart. For this purpose the following experiment was performed: Three small glass jars were placed in a row, and each covered with tinfoil from the centre of which descended a small hook, to which was attached by the aorta the heart of a healthy frog. All three were retained under precisely the same circumstances, with the exception that in the bottom of one jar were a few drops of chloroform, in another a similar quantity of ether, and in the third the same amount of distilled water. The result was, that while the heart that was suspended in aqueous vapor pulsated regularly for an hour or so, that in ether-vapor stopped in less than fifteen minutes, while the one in the atmosphere of chloroform ceased to pulsate within ten minutes. Facts which add still further strength to the foregoing opinion.)

No one, we suppose, at present doubts the fact that the ultimate cause of death in apnœa, no matter in what manner it may be induced, is the absence of oxygen. We may add, that in our opinion this absence of oxygen acts indirectly, and that the extinction of animal life is in consequence of the constituents of the blood not having undergone the oxidation-process, which is essential to the proper performance of their functions when brought in contact with the various tissues and organs of the frame. The confusion of ideas, the unconsciousness, the convulsions, the stupor, the paralysis of the muscles, the stoppage of respiration, the arrest of the heart's action, appear to us to be one and all due to the same cause, *arrested interstitial nutrition*. It is thus seen, then, that what others have hitherto regarded as the primary cause of death in apnœa, namely, the stoppage of the circulation in the lungs, the failure of the heart's action, etc., we look upon as merely the secondary effects of the gradual extinction of life. No one would, of course, venture to assert that the above is of necessity the true explanation of death by apnœa; for all are well aware that, as science advances, new facts may be discovered which may either demand its modification or abandonment; but one thing we may venture to assert, namely, that this "arrested interstitial nutrition" theory is by far the least open to objection of any that has hitherto been propounded, and that it has the advantage not only of giving a rational explanation of the symptoms, and their order of sequence, but is also in perfect conformity with the appearances observed after death.

---

[1] See the author, On the Influence of Physical and Chemical Agents upon Blood, with special reference to the Mutual Action of the Blood and the Respiratory Gases, Phil. Trans., 1865, p. 717.

SECONDARY APNŒA.

We have now to call attention to the fact which has been so frequently observed, more particularly in cases of drowning, that an individual may apparently recover from the primary effects of apnœa, and after the lapse of some minutes, hours, or days, suddenly expire without any apparent cause. This secondary death occurs not only after drowning, but after each and all of the causes of apnœa given in our table. Indeed, it is not much less common after hanging than after drowning; and it has been equally observed after the administration of poisons, more especially of the volatile group denominated anæsthetics.

Lest some may imagine that the secondary form of death now under consideration is nothing more than death following upon imperfect resuscitation, we may at once inform them that it is entirely different. Take, for example, a case of drowning; and we may quote the following, which we heard of in consequence of the gentleman in whose practice it unfortunately occurred being unjustly accused of having treated the case improperly. The patient, a healthy young man, while bathing, accidentally got out of his depth, and before being rescued became much exhausted. On his removal from the water, he was quite unconscious, although the respiratory process still continued. The usual restoratives were applied, and the patient was soon able to speak. He was taken home, and, at the suggestion of the medical attendant, who considered him out of all danger, had some opening-medicine given to him and was put to bed. In the middle of the night, about ten hours after his immersion, he was suddenly heard, by a person who occupied the same apartment, to make a noise, as if in a convulsion. When a light was obtained, it was found that he had become quite livid in the face; and before medical aid could be procured, he expired. At the post-mortem examination nothing was detected to account for the sudden death.

This we regard as a death from secondary apnœa.

Sir B. Brodie relates the case of a lad who was found hanging by the neck insensible, who died twenty-four hours after he was cut down; and at the post-mortem examination nothing abnormal was detected in the body, except congestion of the cerebral vessels.

Linhart, again, relates a most interesting case of a perfectly healthy peasant who died eighteen and a half hours after having been rendered only partially insensible by an ounce and a half of chloroform given in the usual way over a period of thirty minutes. The patient continued perfectly well until the next morning at six o'clock, when he suddenly died. On examining the body, twenty-four hours after death, all the organs were found healthy.

These cases, which have generally been classed under the head of death either arising from collapse or from spasm of the glottis, are certainly peculiar; but nevertheless we consider them as merely the secondary results of the arrested interstitial nutrition that took place during the period that the breathing was partially arrested.

If we may be allowed to use a homely expression, in order to illustrate how the secondary apnœa may arise from a preceding mal-nutrition, we should say that it does so in the same way as a single layer of bad bricks put into a house while building may cause at a subsequent period its premature decay; the layer of bad tissue laid down during the temporary cessation of respiration induces the subsequent premature decay of animal life.

This theory will be still better understood if we illustrate it by what is observed to occur to horses after temporary starvation

Many years ago the French government appointed a commission to inquire into the effects of starvation on cavalry horses; and the results obtained were not only interesting, but most important. Among others, for example, it was found—

1st. That after ten days' total deprivation of food, a horse is still able to gallop, although not very long; and after being again well fed, makes a tolerably rapid recovery.

2d. That a horse may live for twenty days without nourishment of any kind, and still make a temporary recovery.

3. That an animal starved for a certain time, although he makes a temporary recovery never regains his pristine strength, no matter how well fed he may subsequently be.

Thus it was found, that though the horses that had been kept fasting during a period of ten days, and then well fed, apparently recovered rapidly from the effect of the starvation, yet they never were so strong as other horses, and that they succumbed to disease much more readily than others. This failure in the vital stamina, if it may be so termed, we believe was owing to the mal-nutrition that occurred during the previous term of starvation. The subsequent death of the horse might therefore be said to be the secondary result of starvation. The peculiar condition of the red blood-corpuscles which was mentioned as occurring in case of drowning, may in some degree aid in the understanding of what is here termed mal-nutrition, as applied to the secondary apnœa of drowning. It will be remembered that, while abundance of serrated blood-corpuscles was found in the blood of the right side of the heart, there was not only a total absence of them in the watery blood of the left, but that a great number of the normal blood-cells had disappeared; the field being occupied by small granular bodies, looking something like nuclei, that might have escaped from the swollen and burst corpuscles. This observation was of course made upon a fatal, and consequently exaggerated, case; but it is very easy to imagine a less formidable one, in which, during the period of recovery from the effects of drowning, a layer of bad tissue might be deposited from the partially disorganized blood corpuscles, which of necessity would diffuse themselves throughout the circulation along with those that had escaped the pernicious action of the water. We are here speaking of the visible effects of drowning upon the circulation; but how many and intricate are the changes which may have taken place in the blood, during the period of apnœa, that are entirely beyond the cognizance of our senses!

In order properly to comprehend the meaning and pathology of secondary apnœa it is necessary to have a clear idea of the process of nutrition.

It is a common belief that, as we eat and sleep at stated periods, nutrition is not a constant but an intermittent function; an opinion from which we entirely dissent, as not being in conformity with the present state of physiological science. To our mind nutrition appears to be a constant process; fluctuating, it may be, but nevertheless continual. The secretion of milk, urine, bile, and semen goes on during every hour of the day and every minute of the night. It is only the expulsion of the accumulated products that is periodic. So again with food. Just as the camel can pass several days without drinking, if he has previously supplied his reservoir with water, so can man go several hours without eating, if he has previously laid into his stomach a stock of food. The animal, like every other machine, to do constant work must have a constant supply of material. Life, indeed, might not inappropriately be compared to a web of cloth made of the purest American cotton, and each stoppage in nutrition to a flaw. Thus each disease, each temporary illness, although not producing an actual gap, would weaken the web by introducing into it an inferior quality of cotton. It might only be a single thread, or it might be many threads; but still the web would be weakened by their presence. Do we not every day see around us evidence of the flaws in the human webs. Look, for example, at the teeth. Are the furrows we occasionally see across them not the tell-tales of the severe illness of youth? Are they other than the marks of arrested nutrition? So again with the nails; do they not, after a smart attack of scarlet-fever, indicate by their grooves the severity of the illness? Can the falling out of the hair after typhus be said to be due to anything else than temporarily arrested nutrition? Even the mind itself does not escape the general ill. Bad tissue deposited produces bad memory. Old people remember distinctly all that occurred to them in their youth, when good tissue was being laid down; but forget the occurrences of the previous day, when in old age the material is of an impaired quality. So also it is found, and for a similar reason probably, that it occasionally happens that, after a severe illness, little is remembered of what occurred during it. Interstitial nutrition is constantly going on, and it cannot be for an instant interrupted without threatening to bring the machine to a stand-still. Moreover, we might go a step farther, and say that the more quickly it does its work the sooner will its labors cease. Waste and repair cannot go on indefinitely in the animal body any more than in the locomotive. Supply the engine with coals and water as carefully as you will, it will still wear out. That is, however, not the point with which we have at present to deal. It is the temporary arrest of the supply of material we are now considering; and as we have already said, during the period of apnœa it is that supply that is interfered with, and makes the flaw which, although not sufficiently great to produce at once a rent in the web (immediate death), sooner or later causes it to give way (secondary apnœa).

Treatment of Apnœa.

In considering the treatment of cases of impending death by apnœa, it will be advisable, in order to save time and space, first to lay down the general principles on which it is founded, and afterwards to proceed to show in what manner these require to be modified in their application to special cases.

Having ascertained from the history and symptoms that the case is one of apnœa, and not of narcotic poisoning or apoplexy, which, as has been previously shown, under certain circumstances may be confounded with it, the first thing to attend to is the removal of all visible impediments to the natural performance of the respiratory process, and then as rapidly as possible to place the patient under the most favorable circumstances for the reception of a free supply of air. Having done so, time may be taken to inquire more minutely into the state of the patient, and thereby obtain some notion of the probable chances of recovery.

If the eyes are open, the pupils dilated, the conjunctiva insensible, the countenance placid, the skin cold, frothy mucus round the nostrils and mouth, no attempt at respiration, and the heart's action inaudible, the case is hopeless. N. B. As the pulse ceases to be perceptible at the wrist some time before the action of the heart entirely stops, the ear must in all cases be applied to the chest before definitely concluding that the case is hopeless.

If, on the other hand, there is the slightest evidence of respiratory effort, of heart's action, of twitching of any of the muscles, and especially if the apnœa is known to have been of short duration, there is every hope of recovery; and in direct proportion as either or all of the above signs are marked, are the chances of recovery increased. As the primary object in all cases of apnœa is to arterialize the blood as rapidly as possible, various methods for the accomplishment of this object have at different times been proposed. Numerous forms of apparatus have also been invented, in order the more readily to perform artificial respiration, several of which we have tried (Erichsen's, Sibson's, Marcet's, etc.); but we cannot venture to recommend their employment. First, they are not always at hand; secondly, there is no time to send for them, even although they could be procurable in the short space of two minutes; thirdly, they are troublesome in the application; and fourthly, after a pretty large experience with them on animals, we may venture to affirm that they are at last not more effectual than the apparatus-less modes we are now about to describe.

1st. Artificial respiration by simultaneous pressure on the abdomen and thorax.

2d. The Marshall-Hall method.

3d. The Silvester method.

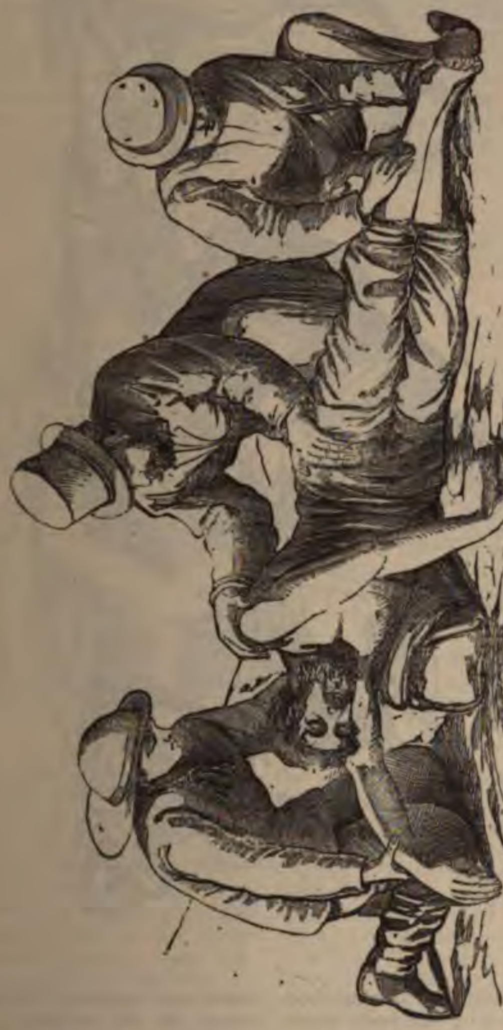
Artificial respiration by simple pressure on the abdomen and thorax.—As is familiar to every one, a certain volume of air can be expelled from the thorax by forcible compression of its walls; on the removal of the pressure, the walls of the chest return to their former position in consequence of their own elasticity, and air rushes into the lungs in order to fill up the vacuum thereby produced. Consequently, by a regular repetition and relaxation of pressure, a species of artificial respiration may be induced, the volume of air inhaled and expelled varying with the amount of the pressure.

When manual pressure equal to about 30 lbs., which is not greater than may be with perfect safety applied to an adult human subject, is made over the lower part of the sternum and upper and middle portion of the abdomen, from 8 to 20 cubic inches of air are expelled and readmitted on the relaxation of the pressure; and by repeating this twenty or thirty times in a minute, sufficient oxygen may be obtained to support life.

In making the abdominal pressure, care is to be taken to observe if any food is forced out of the stomach, which may happen if that viscus is full; and if so, it is necessary that care be taken to prevent it getting into the windpipe. This may be readily done by placing the patient for a few seconds on his face and forcibly expelling the food.

The pressure ought not to be made on the upper part of the sternum, for the resilience of the thoracic walls there is not great enough to allow of the expulsion of sufficient air for the purpose of respiration; nor is the pressure on the abdomen to be omitted, else the diaphragm will descend, and counteract the benefit derived from that made on the lower part of the chest.

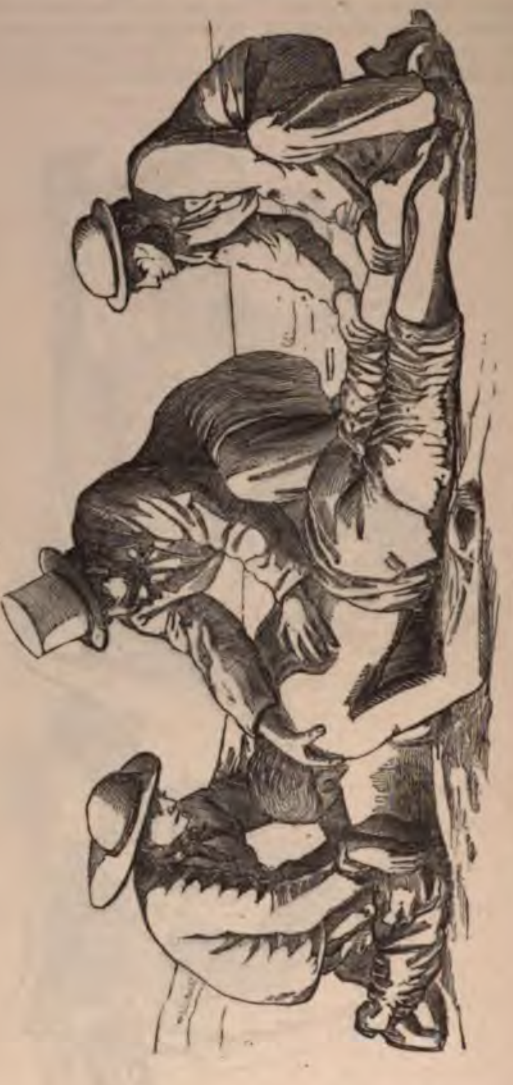
Fig. 565.



Inspiration.

Dr. Marshall Hall's method of performing artificial respiration.—The method of imitating natural respiration recommended by the late Marshall Hall is too well known for us to take up time in describing it; we may simply mention that it consists essentially in "turning the body gently on the side and a little beyond, and then briskly on the face, alternately;" and in making pressure along the back of the chest each time the body is brought into the prone position. Within the last few years this method has been largely practised throughout the country, and most favorable reports of its efficacy have from time to time been published by different gentlemen in the weekly periodicals. Notwithstanding this, however, we must admit that we are extremely sceptical regarding its advantages; and we are doubtful if the recoveries which are reported as having taken place under its use have been attributed to the proper cause. But lest it should be thought that we have an improper bias for any particular method, we shall, in preference to giving our own views regarding the comparative value of the Silvester and Marshall-Hall methods, give the published opinions of the Royal Medical and Chirurgical Society's Committee, with which our own entirely accord. The committee applied the "ready method" and the "physiological method," as they were termed by their respective proposers, to a number of recently dead human subjects, in exact accordance with the published instructions by the authors; and the conclusions they arrived at are the following:[1]—

Fig. 566.



Expiration.

"As regards that part of the method which consists in turning the body alternately 'very gently on the side and a little beyond, and then briskly on the face,' it was found that the volume of air exchanged was variable in the same subject, but always inconsiderable. It usually happened that a quantity of air, varying from 1 to 8 cubic inches, never more, generally much less than 8, was inspired when the body was turned from the supine posture to one side. When the body was placed on the abdomen with the head resting on the forearm, a somewhat larger quantity was expelled, never exceeding 10 cubic inches. On restoring the body to the lateral posture, the amount of air inspired was usually less than that which had been expelled by pronation. But the quantity expelled and inspired in each movement was scarcely ever precisely equal.

---

[1] Med.-Chir. Trans., vol. xlv., p. 488.

"The volume of air expelled when the body was placed on the face was much increased if pressure was at the same time made on the spine, the amount of this increase varying according to the degree of the pressure; and in those experiments in which such pressure was made, it was found that the quantity of air which was inspired on rotation of the body to the side was much less than that which had been expelled by pressure.

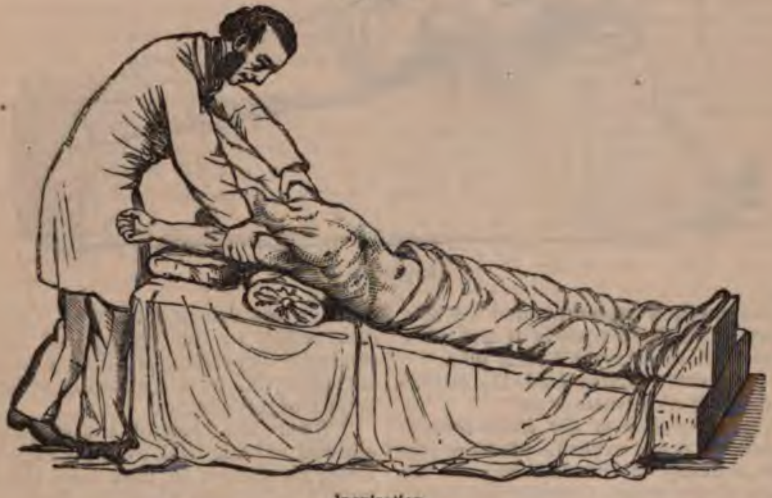
"As regards the whole amount of exchange of air produced by the method of Dr. Marshall Hall, to 'imitate respiration' it varied much according as the subject was favorable or the contrary, sometimes not exceeding a few cubic inches, but never exceeding 15 cubic inches."

Figs. 565, 566 illustrate, more fully than any number of words can, the positions of the body during the employment of Dr. Marshall Hall's method of inducing respiration.

Physiological method recommended by Dr. Henry R. Silvester.—Dr. Silvester's method consists in the imitation of the action during deep inspiration of the pectoral and other muscles passing from the shoulders to the parietes of the chest. The inspiratory effort is imitated by slowly extending the arms upwards by the sides of the head until the elbows nearly touch each other. The expiratory effort is performed by restoring the arms to the sides of the chest, and slightly pressing them against it.

In performing Dr. Silvester's method on the same subjects that were either previously or subsequently employed in practising the "ready method," the committee "found that, on extending the arms upwards, a volume of air was inspired into the chest which varied, in different subjects, from 9 to 44 cubic inches; and it was observed that the results obtained in successive experiments on the same body were remarkably uniform, in which respect, as well as in their quantity or amount, they contrasted with those obtained by the method of Dr. Marshall Hall. On restoring the arms to the side, as directed by Dr. Silvester, the quantity of air expelled was generally nearly equal to that previously inspired; occasionally less.

Fig. 567.

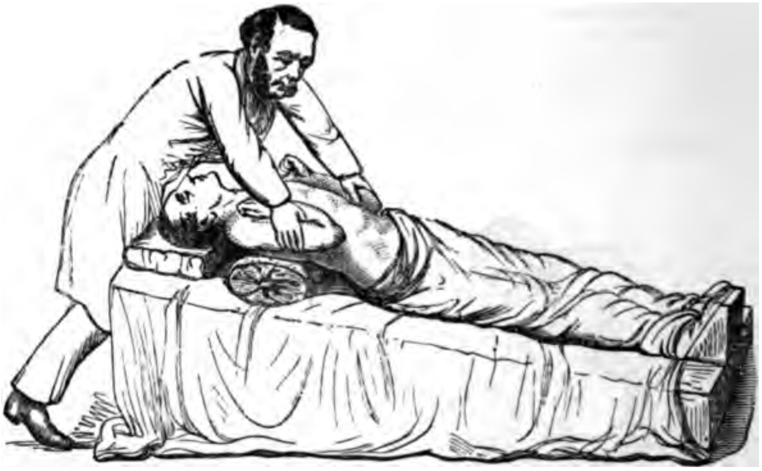


Inspiration.

"Dr. Silvester recommends that on bringing down the patient's arms they should be gently and firmly pressed against the sides of the chest, so as to diminish the cavity of the thorax. It was found that this pressure could be exercised with greater facility, and equal effect, by placing the hands on the lower third of the sternum, as already above described. By alternating the movement of the arms with pressure of this kind, a regular exchange of air was produced, the quantity of which, in several instances, exceeded 30 cubic inches, and in one instance amounted to 50 cubic inches. In those cases in which a less respiratory effect was produced, the deficiency was always distinctly attributable to unfavorable conditions, particularly the existence of obstructions in the respiratory passages.

"Without expressing an opinion as to the efficacy of the method of Dr. Silvester as a means of restoring suspended animation in cases of drowning, its claims to be considered as an effectual means of producing an exchange of air similar to that effected by the respiratory movements appear to us to be satisfactorily established. As has already been pointed out by Dr. Silvester, the condition of the thorax after the cessation of breathing being that of expiration, it is desirable that the first step in the restoration of breathing should be a movement of expansion; in this respect the method he has proposed enjoys a marked superiority over that of Dr. Marshall Hall, which has for its object to force air from a chest which has already discharged its natural quantity. It also appears to be an important advantage in this method, that, in each movement of expansion, both sides of the chest are left free from compression, and therefore free to move, while the postural method of Dr. Marshall Hall leaves only one side free to expand. As regards facility and readiness of application, there is also no doubt that the method recommended by Dr. Silvester is at least equally if not more effective than the Marshall-Hall plan."

Fig. 568



Expiration.

The committee further made the following important observations on

Artificial inflation of the lungs through the mouth.—"A few experiments were performed relating to the efficiency of the inflation of the lungs through the mouth of the subject, which led to the conclusion that with proper precautions such inflation is perfectly practicable. The following were among the results noticed:—

"1. As regards the position of the tongue and its influence in impeding the entrance of air, it was found that in the dead body this organ is apt to offer great obstruction to inspiration by falling back into the pharynx and closing the laryngeal aperture. No air could be forced through the mouth in a body lying on the back so long as the tongue remained undisturbed; but when it was drawn forward and held out of the mouth by a ligature, or by the pressure of the teeth upon it, air could be injected by the œsophagus and larynx, so as to distend both the abdominal and thoracic cavities. On leaving the tongue loose in the mouth, and allowing it to fall back by its own weight, air could also be introduced; but much less freely than when it was drawn forwards. Complete obstruction to the passage of air was produced by pressing the tongue back into the pharynx, no air entering either the larynx or œsophagus.

"When the head of the subject was allowed to hang back over the edge of the table, air seemed to pass into the chest more readily than when the back of the head rested upon the table.

"2. It was found that the whole quantity of air introduced by inflation could be compelled to enter the respiratory cavity by pressing back the larynx against the spinal column. By this expedient the passage of air down the œsophagus was at once intercepted; while its transit down the trachea continued to take place as freely as before, so that it affords a ready means of preventing the passage of air into the stomach during artificial respiration.

"3. During inflation of the lungs, a sound closely resembling that of the ordinary vesicular murmur is plainly heard, proving that air enters not merely the larger air-passages, but the vesicular structure of the lungs. Marked expiratory murmur was also heard during the recoil of the lungs and thoracic parietes after inflation. In cases where the bronchial tubes were obstructed by secretion, the various kinds of crepitation could be distinguished.

"*Rigor mortis.*—The effects of rigor mortis were judged of by observations on one subject especially. It was observed that, after prolonged experiments, the rigidity, which at first existed in a marked degree, was completely overcome and abolished by the repeated movements of the arms and thoracic parietes. As this change took place, the quantity of air inspired and expelled increased, so that at the end of the period of observation the results were nearly twice as large as they were at the beginning."

The committee summed up its labors by making the following suggestions regarding the treatment of apnœa generally; but in giving to them all due consideration, it must be borne in mind that the investigations of the committee related only to two forms of apnœa—that produced by a simple mechanical obstruction to the entrance of air into the lungs, and that produced by drowning. Its conclusions are as follows:—

"That all obstructions to the passage of air to and from the lungs be at once, so far as practicable, removed; that the mouth and nostrils, for example, be cleansed from all foreign matter or adhering mucus.

"That in the absence of natural respiration, artificial respiration, by Dr. Silvester's plan, be forthwith employed in the following manner: the body being laid on its back (either on a flat surface, or better, on a plane inclined a little from the feet upwards), a firm cushion, or some similar support, should be placed under the shoulders, the head being kept on a line with the trunk. The tongue should be drawn forward, so as to project a little from the side of the mouth; then the arms should be drawn upwards until they nearly meet above the head, the operator grasping them just above the elbows, and then at once lowered, and replaced at the side. This should be immediately followed by moderate pressure with both hands upon the lower part of the sternum. This process is to be repeated about twelve or fourteen times in the minute.

"That if no natural respiratory efforts supervene, a dash of hot water (120° Fahrenheit) or cold water be employed, for the purpose of exciting respiratory efforts.

"That the temperature of the body be maintained by friction, warm blankets, the warm bath, etc.

"In the case of drowning, in addition to the foregoing suggestions, the following plan may be, in the first instance, practised: place the body with the face downwards, and hanging a little over the edge of a table, shutter, or board, raised to an angle of about 30°, so that the head may be lower than the feet. Open the mouth and draw the tongue forward; keep the body in this position for a few seconds, or a little longer if fluid continues to escape. The escape of fluid may be assisted by pressing once or twice upon the back."

There are two other methods still to be alluded to: one by Professor Pacini,[1] the other by Dr. Bain. In the former the asphyxiated patient is placed horizontally on a bed or table; the operator, standing with the head against his own belly, takes hold of the patient's shoulders, by applying the thumbs in front of the heads of the humeri, and the four fingers behind and close to the armpits. He then pulls the shoulders towards him, and lifts them in a perpendicular direction, by which means the thoracic cavity becomes enlarged, both in its transverse and antero-posterior diameter, thereby admitting the ingress of air, which is expelled on the shoulders being replaced in the former position. If the patient is on the ground, the operation is performed by the practitioner while kneeling.

Dr. Bain thus describes his method: "The patient being laid on his back on a table, if convenient, the mouth and nostrils are to be wiped dry—the clothes from the upper part of the body, at least, having been removed. The operator stands at the head of the patient, placing the fingers of each hand in the axillæ, in their front aspect, with the thumbs on the clavicles, and pulls the shoulders horizontally towards him with a certain degree of power. Upon relaxing his pull the shoulders and chest return to their original state."

These two methods are therefore but a mere modification of Silvester's plan, the modification consisting in the upper, instead of the lower, part of the arms of the patient being the point of traction.

A committee appointed by the Roy. Med. and Chir. Soc. examined these respective methods, and found that although more air can be made to enter the chest when the traction is made upon the shoulders instead of the forearm or arms, the difference is so slight that in the great majority of cases it is of comparatively little moment which method of manipulation is practised, provided the common principle on which they are founded is fairly carried out.[2]

Having said thus much on the general bearings of treatment in cases of apnœa, we have now to consider some of the special bearings as applicable to particular cases. It will be remembered that we classified the different forms of apnœa under the four heads of— that arising from a mechanical impediment to the entrance of air into the lungs, that produced by drowning, that caused by an absence of oxygen in the inspired medium, and that due to the inhalation of a toxic gas or vapor. As regards the first of these causes; it ought never to be forgotten that apnœa may arise from mechanical causes, and yet, *even while the cause exists* it may fail to be detected, and the patient be allowed to die in consequence. This happened not long ago. A cabman, sitting on the step of his cab, eating his dinner, was suddenly hailed by a fare. He jumped up, pushed the remainder of his meal into his pocket, sprang on to the box and seized the reins, when immediately afterwards he was observed to become livid in the face, and with scarcely a struggle fell back insensible on his seat. A hospital being close at hand, he was instantly conveyed thither; but although only a few minutes had elapsed, he was found to be dead almost as soon as he was brought into the waiting-room. The case was thought to be one of apoplexy, and was treated as such; that is to say, nothing was done; no attempt at resuscitation was made; and it was not until the autopsy revealed the true cause of death that the idea occurred that the man's life might have been saved. A piece of unchewed meat was found sticking in the throat and plugging up the opening into the larynx. There can be but little doubt that if this had been discovered and removed when the man was first brought into the hospital, its removal, in all probability, would have been followed by recovery, either with or without artificial means. Cases of this kind are not so very uncommon. Several have been reported in the journals.[1] It ought also to be borne in mind that suicide and even murder have been committed by thrusting substances into the fauces. A pocket-handkerchief is said to have been the instrument in one case; a ball of cotton in another.

[1] Di un nuovo Metodo di praticar la Respirazione artificiale.

[2] Trans. Roy. Med.-Chir. Soc., vol. liii.

It also occasionally happens that children are suffocated in attempting to swallow their playthings. In 1851, we saw Trousseau rescue a child from impending death by the timely performance of tracheotomy, and the extraction of a cherry-stone which had become lodged in the trachea. It is not necessary even that the plaything enters the trachea; if it be of considerable size, as in the case of a whistle, it may stick in the œsophagus, and by its pressure on the trachea obstruct the entrance of air into the lungs.

Feeble children, and still more frequently intoxicated adults have been suffocated from food ejected out of the stomach getting into or blocking up the orifice of the trachea. A drunken man perished once after vomiting, from a piece of potato-peel covering the glottic orifice. The cause of death remained unknown until it was revealed at the post-mortem examination.[1]

On more than one occasion it has happened that not only during life, as in the above cases, but even after the autopsy, and until a second and more searching examination of the body has been made, the true cause of the apnœa has failed to be detected.

It may be useful, perhaps, to know that in nearly all cases of plugging of the respiratory passages, a clue may be obtained to the mischief by the lungs refusing to collapse on the chest being opened. This of course arises from the air contained in them being unable to find an exit in the usual way.

As regards the accidental suffocation of children by bedclothes or wearing-apparel too closely covering their faces, we would remark that this accident, which has ocsionally arisen from excessive care as well as excessive carelessness, the practitioner is in some cases able to remedy. Cases of this kind, when seen sufficiently early, are admirably adapted for treatment by artificial respiration. There being no violence or injury of any kind either to the air-passages or to the lungs, death arises from non-arterialization of the blood in one of its least complicated forms. So that, if the heart's action is still perceptible, no matter how feeble it may be, the chances of recovery by artificial inflation are exceedingly great. We have just said that this accident may happen from excessive care; a good example of this occurred not long ago. A young mother, while carrying her first-born to church to be baptized, in order the more effectually to protect it from the cold, turned up the end of her shawl, and drew it over the infant's head. On arriving in church and uncovering her charge, she for the first time discovered that her excessive care had proved fatal to her child.

In a case of this kind inflation should be had recourse to, even after the heart's action has stopped; and it should be continued for at least a quarter of an hour or twenty minutes. We have seen new-born children recover after that period from suffocation.

---

[1] In University College Museum is a preparation which illustrates admirably how firmly the larynx may get plugged with a fragment of unchewed meat.

[1] Edin. Med. and Surg. Journ., 1844.

Artificial respiration in infants is to be done differently from any of the modes we have hitherto described. The muscles of the new-born are not sufficiently developed to make the Silvester method effectual; and as for the Marshall-Hall and the manual-pressure methods, in cases of still-birth they are simply impossibilities; for, as the child has never breathed, there is no air in the lungs to expel, either by one or the other method. Even if the child has breathed, the thoracic walls are scarcely sufficiently strong and elastic to enable these methods to be adopted with much prospect of success. In children, at least under six months old, mouth-to-mouth inflation is by far the simplest and most effective mode of artificial respiration.

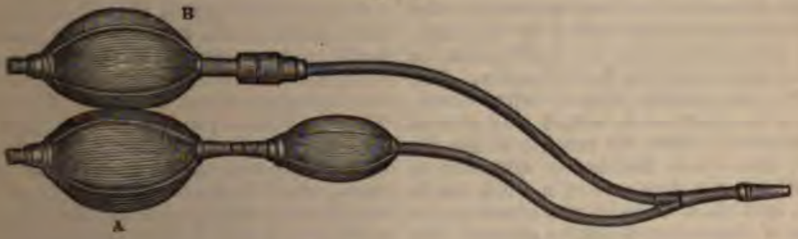
The operation is best performed by placing the child on a pillow on the table, with its head to the operator's left hand. The operator placing himself on a chair, after wiping the mouth and nostrils clean, should seize the larynx between the thumb and forefinger of the right hand, and press it gently but firmly upwards and backwards. This is done with the object of facilitating the entrance of air into the lungs, and at the same time preventing any passing down the œsophagus into the stomach. The nostrils are then closed with the left hand, and the operator proceeds to distend the child's lungs with air by placing his lips over its mouth and blowing steadily into it. Having done so, he removes the hand from the larynx and gently aids in the re-expulsion of the air from the lungs by pressure on the lower part of the sternum. This is to be repeated twenty or twenty-five times in the minute. We have frequently adopted this method, even on premature children, with perfect success. As an example of this mode of procedure, the following case, which to us is one of more than usual interest, may be related:—

In 1850, while house-surgeon to the Royal Maternity Hospital in Edinburgh, we extracted a child by the Cæsarian section after the death of the mother.[1] It was only a seven-and-a-half months' child, and on extraction neither pulsation in the cord, nor the slightest movement of the heart, was perceptible. Mouth-to-mouth inflation was immediately had recourse to, in the manner above described; and after at least ten minutes' labor it succeeded in restoring the heart's action, which was soon afterwards followed by respiratory movements, which, though feeble for a time, soon became sufficiently strong for the purposes of life. After the lapse of nineteen years the individual was ascertained to be still alive, and a fine healthy young man.

It is sometimes no agreeable task to apply the mouth to that of another. In that case a flexible or a metallic catheter may be passed into the trachea, and tightly held there by the finger and thumb placed on the neck, while air is blown through it into the lungs. The only difficulty here is the getting the instrument into the larynx; but that is easy enough if the operator will only remember to take the precaution to push the larynx upwards and backwards, as before described, and then glide in the catheter with its point tilted forwards. The catheter will be known to be in the trachea, and not in the œsophagus, by our capability of moving the larynx from side to side by its means.

Dr. Richardson[2] has proposed a "pocket bellows" for artificial respiration, as represented in the accompanying woodcut.

Fig. 569.



It consists of two elastic hand bellows ending in a single exit tube. When the bellows are in action, the tube being inserted in the nostril, one ball (A), after exhaustion, becomes filled from the common air, and the other (B) from the air left in the air-passages. During compression, the air in the ball charged with common air enters the lungs, and the air in the ball charged from the lungs is driven into the atmosphere. Thus the precise conditions of natural respiration are imitated. The filling and emptying of the lungs is in the grasp of the operator, who can therefore fill or empty gently or forcibly, as he pleases. In using the bellows, it is good to begin by a gentle exhaustion, and the milder the force employed to fill the lungs. the better. Merely to excite thoracic movements is sufficient, and the moment there is spontaneous or natural breathing, it is best to cease the artificial process. In croup and other diseases where the air-passages are obstructed, and the patient is sinking from exhaustion of the muscles concerned in respiration, Dr. Richardson thinks these bellows may be employed with great benefit.

---

[1] Edin. Monthly Med. Journ., July, 1850.

[2] Med. Times and Gaz., December 4, 1869.

In cases of apnœa from inflammation of the fauces, excited by drinking boiling water, inhaling steam, or swallowing escharotic fluids, it is better, before attempting artificial respiration, at once to perform tracheotomy. For when the inflammation or disorganization is sufficiently severe to prevent the entrance of air by the natural thoracic movements, it is not at all probable that artificial means will be more successful in surmounting the obstacle to its admission. The same remark is equally applicable to cases of diphtheria and croup.

In cases of attempted death by strangulation, the surgeon may be called upon to treat something else than mere apnœa. If much force has been employed in constricting the neck, there may be considerable injury done to the larynx. The os hyoides may be fractured; the laryngeal cartilages broken, especially in old persons, in whom they have become ossified; moreover, there may be contusion, and even laceration, of the soft parts of the neck. As an illustration to these remarks, the following case of impending apnœa arising from fracture and displacement of the os hyoides may be cited:—

On May 28, 1856, a little girl, aged six years, while jumping, fell with her neck across the rail of an iron bedstead. She was instantly seized with a fit of coughing, great dyspnœa, an inclination to vomit, and a copious flow of saliva. The saliva was partly tinged with blood. When brought to us, which was almost immediately after the receipt of the injury, there was distressing difficulty in breathing, the face was of a livid blackness, and there were all the other symptoms of impending death by apnœa. On examining the neck, there was found a sharp body projecting beneath the skin. It was very angular and quite movable. On close inspection it was found to be the displaced ends of the fractured hyoid bone. One end of the body rode over the other. By a little manipulation the fracture was reduced, and all the symptoms of impending suffocation, together with the copious flow of saliva, etc., rapidly subsided. A bandage was placed round the neck to keep the ends of the bone in their place; and with the exception of a smart attack of fever, which lasted three days, the child made an uninterrupted recovery, and without any deformity except a slight fulness caused by the callus; but even this after a time disappeared.

Where there is much congestion of the vessels of the head and neck, bleeding has occasionally been had recourse to; and although it cannot be recommended as a means of removing apnœa, yet we see no reason for condemning it *in toto*, as some recent writers have done. On the contrary, although we would not advise it to be practised as a general rule, we nevertheless think that the abstraction of a moderate amount of blood from the right jugular vein may be sound treatment in certain cases of apnœa. It will have the advantage of relieving, for a time at least, the congestion in the vena cava superior, and thereby facilitating the contractions of the over-distended and thereby weakened heart. On opening animals immediately after death by apnœa, we have frequently seen the arrested heart's action recommence, and continue regular for at least a quarter of an hour after we had punctured the vena cava and thereby relieved the engorged cardiac organ of some of its blood. The heart is exactly like the bladder; whenever it is over-distended, it ceases to be able to contract upon its contents. In thus recommending bleeding from the jugular vein in certain cases of apnœa, we desire it to be distinctly understood that the abstraction of blood is only to be regarded in the light of an auxiliary to the other treatment, and to be in no case practised except in plethoric subjects; for, in those of an opposite constitution, all the blood they possess is required to carry them through the dangerous period of secondary apnœa.

It has been argued that if bleeding is serviceable at all, it ought to be particularly so in cases of strangulation and hanging, where urgent symptoms of cerebral congestion are frequently observed. No doubt this view is correct; but the bleeding must not be carried too far, for experience has taught that in these very cases, after the first insensibility has been temporarily recovered from, bleeding has neither prevented the supervention of stertorous breathing, convulsions, coma, nor even death itself.

As regards treatment in cases of drowning, we desire to call special attention to the fact, that all persons who die in the water are not necessarily drowned. A man laboring under heart-disease may suddenly expire from the thoracic shock received in coming violently in contact with the surface of the water. Persons falling from a height have died from concussion of the brain and extravasation of blood under the arachnoid.

On the other hand, persons have died of apoplexy while bathing; and not long ago the brother of a medical man died from an epileptic seizure which was supposed to have come on during the act of diving. This occurred in one of our public baths, where he was in the habit of practising swimming. On the occasion in question he was seen to dive, as he usually did on first entering the water; but as he never rose again, a search was made, and his lifeless body was found lying at the bottom of the bath. The gentleman had suffered from epileptic attacks for several years.

While guarding against an error in treatment from mistaking epilepsy for drowning, one must be equally cautious not to fall into the opposite error of mistaking the convulsions of apnœa for those of epilepsy; for they may occur in cases of drowning, as well as in any of the other forms of death from cessation of the respiratory process.

As regards prognosis in cases of drowning. It may be laid down as a rule, that the more complete the submersion the more fatal the case; for after the person is completely submerged, frequent attempts at respiration continue to be made, with each of which air and frothy water are expelled from the lungs, and water enters. This goes on until the person is exhausted and all attempts at respiration cease. For example, a person completely submerged for one single minute and a half has a much slighter chance of recovery than one who has struggled about in the water for ten minutes or more, even although the former when taken out is still making efforts at respiration, and the latter has ceased to do so. Of course it is taken for granted that in the latter case the heart's action still continues, and the respiratory movements have only just ceased. The heart's action continues for from two to four minutes after respiration has stopped; and so long as the impulse of the heart is perceptible, resuscitation is not only possible, but probable.

By referring to the physiology of drowning, the grounds upon which this assertion is based will be at once evident. It may be added, as a second general rule, that the more rapid the cessation of the respiration in cases of drowning, the less is the chance of recovery—which is exactly the reverse of what happens after apnœa from mechanical obstruction. The reason of the greater likelihood of death after a rapid stoppage of the respiratory movements in drowning, is that it usually arises from a very sodden condition of lung; and in proportion as the lungs are sodden with water are the chances of recovery diminished. When the person has gone on struggling for some length of time, and occasional imperfect inspirations have been obtained, he at length sinks from the combined effects of exhaustion and apnœa, and the lungs are not then in the sodden condition met with in cases of entire and continued submersion. This, too, is the reason why the lungs of human beings seldom or never exhibit the excessively sodden condition met with in animals sacrificed for experiment.

The object of suspending drowned persons by the heels for a second or two is to permit of the exit of the water from the trachea and bronchi; and the plan is no doubt, in certain cases, a good one.

As regards the treatment of cases of apnœa from simple absence of oxygen in the inspired medium, we have no special remark to make, except that artificial respiration is the only treatment required.

While regarding the cases of semi-apnœa and semi-poisoning of the fourth group of the classification, we have to observe that, if possible, artificial respiration is more imperatively demanded in them than in any of the other cases we have hitherto been considering, for the simple reason that not only is oxygen required to be put into the circulation, but the poisonous gas to be taken out; and there is no readier means of attaining this object than by artificial respiration. All gaseous and volatile poisons are much quicker eliminated by the lungs than by any other channel. A most striking illustration of this can be given in the experiment first proposed by Bernard, and which we have several times repeated with results precisely similar to those obtained by its inventor.

Sulphuretted hydrogen, when inhaled, is rapidly fatal to animal life; whereas if, instead of allowing the gas to enter the circulation by means of the lungs, it be mixed with water and injected into the jugular vein, it fails to produce any toxic effect. And why? Merely because it is *exhaled* by the lungs during its passage through them, and it is thereby prevented from getting into the arterial current. So rapid is the exhalation of the gas, that if a fragment of white paper moistened with the acetate of lead be held in front of the dog's nose, within four seconds after the injection of the gas into the jugular vein, it reappears in the expired air; as is proved by the black sulphuret of lead which forms on the paper the moment the breath comes in contact with it.

The experiment is sufficient of itself to prove the value of artificial respiration as a means of eliminating volatile poisons from the circulation · so that it is unnecessary for us to enter into the question of the pulmonary elimination of ether, chloroform, or any other volatile vapor or gas; the results obtained by experiments being identical in all cases, as far as they have been yet tried.

In entering a place full of foul air, for the purpose of rescuing some one who has become insensible, a deep inspiration should be taken, and then the breath held the whole time the person is in the poisonous atmosphere; just in the same way, and for similar reasons, as a man fills his chest with air before diving, and holds his breath the whole time he is under water. It might be said that these views are still further supported by the facts discovered by the Committee of the Royal Medical and Chirurgical Society, namely, that while a dog submerged for a minute and a half without being previously chloroformized, dies, a dog, previously rendered insensible by chloroform, may be submerged for two minutes fifteen seconds, and yet recover. It is thus seen that by simply depriving the animal of the power of making voluntary respiratory efforts, the period during which submersion may be continued, and yet recovery follow, is at once prolonged.

It only remains for us now to put before our readers the general rules which should guide them in the treatment of cases of apnœa, the fundamental object which is to arterialize the blood as rapidly as possible. The Royal Humane Society's rules are so admirably drawn up, that we have only to modify them a little in order to give to them the wider application demanded by the general question of apnœa.

Galvanism has been frequently proposed as an aid to recovery in cases of suspended respiration; but as the grounds on which its supposed benefits rest are somewhat vague, they need not be here entered upon. The advantages derivable from the remedy may be summed up in a very few words. In the first place, it is to be borne in mind that artificial respiration cannot be kept up by galvanic influence alone. Galvanism can only be employed as a direct re-exciter of normal respiratory movements and reawakener of the heart's action, when that organ has ceased to pulsate. For these purposes it is best employed in conjunction with artificial respiration; and is most readily applied by placing one pole in the upper sternal or lower cervical region, and the other immediately over the diaphragm. The galvanic shocks ought not to be too frequent nor too prolonged; and when they visibly fail to restore the normal respiratory movements and cardiac action, this agent ought to be laid aside, as its continued use tends to exhaust the vital energies.

RULES OF TREATMENT IN CASES OF IMPENDING DEATH BY APNŒA.

1. All froth and mucus, of which there is usually a considerable quantity, are to be immediately removed from the mouth and nostrils; and should the case be one of drowning, in addition to the removal of the mucus from the mouth and nose, the legs and trunk of the patient are to be raised for a few seconds above the head and shoulders, in order to allow of the exit from the trachea and lungs of any free fluids that may be present in them.

2. All tight articles of clothing are to be at once removed from the neck and chest. For example, the cravat **is to be taken off,** the shirt unbuttoned, **the corset unloosened,** etc.

3. Should it happen **that the patient is** already so **nearly dead** that **his tongue sinks back into the fauces, and is thereby likely to interrupt the entrance of air into** the trachea, **it is to be drawn forward,** and, if necessary, **held there.**

4. If the **respiratory movements have** ceased, or become **few and feeble, artificial** respiration **is to be performed by manual** pressure, or **by the Silvester method.**

N. B. **In order to do this readily, place the patient upon his back upon a flat surface, with the pillow or cushion under** the shoulders, **for the purpose of arching** the back slightly; **and if manual pressure** is the method **adopted, it must not be forgotten** that **the pressure is to be made simultaneously** on the lower **part of the** chest and middle **of the abdomen.**

5. Should the apnœa **be the result of** mechanical constriction **of the chest, as** from a fall of earth **or stones, by which** one or more of the ribs **may have been** broken, the manual pressure **and the ready** methods are to be avoided, **and artificial** respiration **by means of the Silvester** method employed **in their stead.**[1]

---

[1] If there be sufficient assistance at hand, the Silvester method may be followed in all cases in which artificial respiration is considered necessary; but where the medical attendant is alone, the method by simple pressure is the quickest and easiest that can be adopted. It only differs from the Silvester method in this respect, that in it the air is forcibly expelled from the lungs, and allowed to enter, in consequence of the vacuum produced in the thorax by the re-expanding of the walls by their own elasticity; while in Silvester's method the air is forcibly inhaled and then expelled by the natural resilience of the ribs. In both cases the respirations should amount to twenty, thirty, or even forty per minute. The natural respirations are only eighteen per minute; but in cases of resuscitation, our object is to arterialize the blood even more rapidly than in health;

6. As soon as natural respiratory movements recommence, cease the employment of artificial means, unless the efforts are feeble and imperfect, when they may still be aided for a time with advantage.

7. As soon as the patient is capable of swallowing—and sooner, if a stomach-pump is at hand—administer a cupful of warm coffee or tea, with a couple of drachms of spiritus etheris nitrici in it; or if that is not at hand, a tablespoonful of brandy or other spirit.

8. Use warm frictions all over the body, more especially on the limbs, to aid the circulation; and the more the skin is exposed to dry warm air the better, as even the cutaneous respiration aids in the arterialization of the blood.

9. When the temperature of the body is much reduced, as in cases of drowning during the cold winter months, try and restore it by means of a hot-water or air-bath. If by the latter, place the head of the patient so as to keep the rarefied hot air from entering the lungs. Artificial respiration by pressure and frictions with the hand can both be readily applied while the body is in the warm bath.[1] The bath should not be too hot (not above 106° F.), as it is not desirable, for the reasons formerly given, to raise the bodily temperature above its normal standard. Nor should the body be retained in it after the temperature has been restored; for, as was before said, the more the skin is exposed to the air the better.

Treatment after the breathing has become natural.—1. Give the patient some warm nutriment, to which a small quantity of stimulant is added; beef-tea, chicken-soup, coffee, or simple tea with one or two tablespoonfuls of brandy.

2. Put him into a well-aired bed with hot bottles to his feet, and encourage sleep.

3. Let him be carefully watched during sleep in case of secondary apnœa; at the slightest symptom of which let gentle frictions and, if necessary, artificial respiration be again had recourse to. Give volatile stimulants, such as the spiritus ammoniæ aromaticus, or spiritus etheris nitrici.

In the case of the drowned, the following might be said to be the four golden rules of treatment:—

1. Empty the air-passages of all the water and frothy mucus they may chance to contain, by holding the legs and trunk higher than the head.
2. Wipe the mouth and nostrils dry.
3. Draw forward the tongue.
4. Use artificial respiration.

---

and as we cannot introduce by artificial means the same amount of air that is taken in by the normal efforts, we must increase the number of our respirations.

[1] In the case of a young woman, one of the fourteen who were nearly drowned in the water at the Regent's Park a few years ago, in consequence of slipping into a hole in the ice, the body was so excessively cold, and the limbs so stiff, that as soon as she was brought into the tent which was being used as a temporary receiving-house, she was instantly put into a warm bath, without waiting to take off her clothes, and artificial respiration by manual pressure at once commenced. It was, however, found impossible to obtain any result with her stays on; so they were slit open, but not removed, and the artificial respiration at once recommenced. In about twenty minutes the patient was so far recovered as to be able to give her address. In this case, when brought into the tent, the girl appeared to us to be perishing as much from the effects of cold as from apnœa.

DISEASES OF THE BONES, JOINTS, AND MUSCLES.

DISEASES OF THE BONES.

By T. Holmes, Esq.

Revised by Thomas M. Markoe, M.D.

Diseases of the bones may be conveniently divided into the following classes: —*First*, inflammation and its consequences: under which head it is proposed to include the varieties of the inflammatory process, which have received the names of periostitis, osteitis, and osteo-myelitis; and, as consequences of these, all the numerous conditions which have been confounded together under the common but vague designation of caries, the various forms of suppuration in bone, the varieties of necrosis, its effects, and those processes of repair which result in permanent modification of the structure and form of the organ. The *second* class will include the specific diseases, which occur either as modifications of the inflammatory process—syphilis, scrofula, and rheumatism in bone—or as constitutional conditions leading to changes in the bony structure; such are, mollites ossium, rickets,[1] and cancer. The *third* division will comprise a description of the various new formations found in the osseous system, and which are not dependent on any of the known constitutional cachexiæ. The *fourth* will treat of atrophy and hypertrophy properly so called, *i. e.*, uncomplicated by inflammation.

Simple Inflammation and its Consequences.

Inflammation of bone differs from inflammation of soft parts, not in its essential, but in its accidental features; the inflammatory process is the same, but the conditions and circumstances are different, and hence arise diversities in rate of progress, in external appearance, and in other symptoms; diversities which, although they are not really essential, yet cause striking differences to ordinary observation, and have led to the designation of the results of inflammation in bone by names differing from those which are used for the same changes in soft parts. This difference in nomenclature, though it might arise in mistake, at a time when necrosis was thought to be something essentially different from gangrene, and caries a disease which had little in common with ulceration, is yet hardly to be regretted, since the diseases of bone, though pathologically identical, are practically very different from those of soft parts; and it is convenient to have separate names for things which require very different treatment, and entail a very different amount of danger.

If the reader will consult the appendix to the essay on Inflammation in Vol. I. of this work, he will find abundant information on the early steps of that process. These affections are identical in bone and in soft parts; in fact, they can occur only in the soft parts of bones, since the mere inorganic matter, which, involved in the convolutions of a cellulo-fibrous and vascular network, constitutes a bone, can itself be the seat of no vital actions, but must obey the movements impressed upon it by the living textures around.

In Von Bibra's essay *On the Decomposition of Bone by Caries*,[1] will be found a good deal of interesting information on the chemical and microscopical characters of bone inflammation; and from this author's researches it appears clear, that the changes in the inorganic constituents of bone are often limited to the dissolution of that connection which previously united them to the organic matrix, so as to form one system. This connection having been severed, portions of the salts are washed away in the discharges, and they may be found, according to Von Bibra's account, in unaltered chemical composition, while the composition of the organic constituents of the same part is profoundly changed, principally by that fatty degeneration which occurs in all inflammations. The inorganic constituents must, however, in some cases of inflammation undergo other changes, since they may disappear in large masses, without any discharge having been present. Thus in caries of the spine, or in inflammation excited by the pressure of tumors, it is not rare to find that large portions of the vertebral column have been removed, sometimes to such an extent as to expose the spinal canal; yet no abscess has formed. The older pathologists made a distinction between these cases and those of caries, founded on the presence of pus in the latter, and its absence in the former; but this distinction, though of great practical importance, does not indicate any pathological difference. Both are inflammatory processes, though of different degrees: the one, ulceration attended by suppuration; the other, ulceration attended by liquefaction only. From this fact of the disappearance of masses of hard tissue, without any discharge in which they can have been washed away, it seems clear that the small earthy particles thus loosed from their natural connection with the organic matrix may undergo a reversal of the process by which they were deposited out of the fluid blood; *i. e.*, may become again soluble, and pass into the venous current.

---

[1] The subject of rickets, however, will not be found here, as it has been thought better to refer it to the Surgery of Childhood.

[1] Liebig und Wohler's Annalen, vol. lvii. It will be found useful to compare this essay

The earliest microscopical change[1] is an unusual fulness and distinctness of all the vascular cavities of the bone; the Haversian canals, lacunæ, and canaliculi being all more sharply marked than in the natural state. This Von Bibra compares to the injected condition of soft parts. Later on, the Haversian canals and lacunæ become widened; the latter disappear in consequence of the communication of neighboring cavities, and spaces are formed in the bone, filled with fat and earthy salts, the detritus of the decomposed tissue.

The earliest change in the consistence of bone, produced by inflammation, appears to be softening; as a consequence of the loosening and absorption of the mineral portion, and the liquefaction and conversion into fat of the organic matrix. Mr. Barwell has published an interesting essay "On Osteitis,"[1] which affords, perhaps, the most distinct demonstration of the enlargement of the vascular spaces at an early period of inflammation. In this essay, Mr. Barwell teaches that the earliest stages of inflammation are accompanied by induration; an assertion which I venture to question, since it appears to me that induration is a phenomenon subsequent in order to the inflammatory process in its stricter sense, and due to one of its results, viz., effusion. The reader is referred to the original essay, which will well repay perusal.

Such are the earliest changes in the minute structure and consistence of inflamed bone. The changes which take place in its rough anatomy may be thus described. If a bone be examined at an early period of inflammation (the ordinary and most accessible is the stump of the bone in an amputation fatal, say, three weeks after the operation),[2] the periosteum will be found somewhat thickened, vascular, and not so closely connected to the bone as usual.[3] If the periosteum be stripped off, the bone is seen to be irregularly vascular, some portions of it having a slightly red tint, and contrasting with the healthy white color of the rest of the bone. This red tint is evidently caused by the enlargement of the vessels which pass from the periosteum into the bone; and if a magnifying-glass be used, the increased size of the vascular apertures is easily proved, while if pressure be made on the surface of the bone, drops of blood will frequently ooze from the mouths of the enlarged vessels, proving their increase in size, as well as the loss of consistence in the outer hard wall of the bone. At the same time there will be found, in all probability, on some other part of the surface, more or less deposit of osseous matter, which, with the partial separation of the periosteum above mentioned,

with those of Mr. Barwell and Dr. Black, referred to further on.

[1] See Von Bibra, op. cit.

[1] Brit. and For. Med.-Chir. Rev., April, 1860, pp. 460 et seq.

[2] In such a specimen the periosteum will generally be found stripped off from a small ring at the lower end of the bone, and this part will perhaps be dead or about to die; but as this feature is accidental, it will not be further noticed.

[3] Hunter has put up (Mus. Coll. of Surg. No. 656) "A preparation of a femur, which was amputated, with the periosteum separated; to show how clear the periosteum separates from the bones in inflammation; a fact almost always observable after amputation."

testifies to the fact of effusion from the vessels of that membrane. In these simple cases of injury the deeper parts of the bone will probably be unaffected; but should this not be the case, *i. e.*, should inflammation have also attacked the membrane lining the medullary cavity and cancelli, that membrane will be found in a condition essentially analogous to that of the periosteum, although the different situation of the medullary membrane, and the great quantity of fat and other loose tissues among which its vessels run, will somewhat modify the external appearances. If, however, these appearances be minutely investigated, they will be reduced to: increase in the number and size of the vessels, and effusion of blood, lymph, or pus, according to circumstances. The thickening both of the periosteum and of the medullary membrane is sometimes considerable. The former membrane is, of course, more frequently found thickened than the latter; but preparations showing the participation of the medullary membrane in inflammation of the bone, and the identity of its appearance with that of the thickened periosteum, are not wanting.[1]

Thus we see that when inflammation commences, as it usually does, on the surface of a bone, whether periosteal or endosteal, its primary symptom is increase in the size (and perhaps number) of the capillary vessels, or vascular spaces, and effusion of blood or lymph. The primary effects of inflammation in the central parts of the compact tissue are similar to the above; though here, from the different circumstances in which the vessels are placed, this similarity has been less distinctly perceived; and from the slowness with which all changes go on in the compact tissue, opportunities rarely occur of comparing the different parts of the same bone with each other. The first change is the enlargement of the vessels which run in the Haversian canals; but effusion is a much later phenomenon, and is preceded by the absorption of the bony tissue which adjoins the enlarged vessels; so that in microscopical sections of inflamed bone, the Haversian spaces are seen much enlarged, irregular, eroded, and sometimes almost, or quite, communicating with each other. The lacunæ may also be noticed to be densely crowded together, and sometimes the granular matrix of the bone appears more coarse than natural. When this absorption of the walls of the Haversian canals becomes visible to the naked eye, the first change in the rough anatomy of inflamed compact tissue becomes appreciable—that in which spaces are seen in it on section like those in cancellous tissue, so that it is sometimes said to become cancellous. Similar changes occur in the cancellous tissue itself, whereby its cells become much enlarged, and sometimes the whole bone is expanded by the simultaneous yielding of its walls.[1]

[Cornil and Ranvier say that "the first change in a bone upon which artificial irritation has been employed is the formation of embryonic cells in the medullary spaces, in the Haversian canals, and under the periosteum. These cells resemble those which fill the primary medullary spaces during the development of bone from cartilage, or those which are found under the periosteum while the bone increases in thickness. Irritation of a bone results, then, in its return to an embryonal condition, and herein we find an application of the general law which governs the irritation of any tissue."

O. Weber and Volkmann consider the absorption of osseous tissue to depend upon a fatty degeneration of the bone corpuscles. Billroth asks, "Is there such a thing as inflammation of the bone substance proper?" and answers the question in the negative, chiefly because he considers the physical conditions of compact bone incapable of swelling, and other changes which, as he considers, must characterize all real inflammations.]

Into the spaces thus hollowed out in the substance of the bone, or on its surface by the removal of the earthy matter, the products of inflammation are next secreted. These secretions vary, of course, according to numerous preceding circumstances, *e. g.*, the nature of the injury, or other cause of inflammation, the activity of the process, the constitutional condition of the patient, and a thousand others; and so the products of osteitis are divisible into two principal varieties, corresponding to the plastic and aplastic lymph met with in other parts, and leading, the former to the deposition of earthy matter and the formation of new bone, and the latter to suppuration. The former result terminates in hardening, or *sclerosis*, as it is termed; the latter in a variety of conditions: when the suppuration is limited within a cavity in the cancellous tissue, or in the compact tissue rarefied by previous inflammation, *circumscribed abscess* is produced; when the pus extends along the inner surface of the membrane lining the medul-

[1] See a description, by the author, of the bones of the lower extremity ten months after excision of the knee, where the superficial laminæ of the femur had been so separated from each other by inflammation that the bone crackled under the pressure of the finger. Path. Soc. Trans., vol. xii., p. 171.

[illegible] inflammation of the [illegible] the death of larger [illegible] of gangrene, is often [illegible] inflamma- [illegible] of necrosis must [illegible]

[illegible] separately the causes, [illegible] and treatment of each of these [illegible] of the inflammatory process [illegible] intended only as a sort of ground-plan to mark out the various parts of a rather intricate subject, each of which must be studied in detail.

Osteitis.—Inflammation of bone is excited [illegible] by external violence, or exposure to cold, acting upon a constitution predisposed to the disease. The chief predisposing causes are the syphilitic or scrofulous taint, rheumatism, and defective nutrition; or these may themselves set up inflammation in any bone, without a distinct exciting cause. From this mode of causation it follows, that the bones most liable to inflammation are those most exposed to the action of external agents. Hence we see it most frequently in the tibia among the long bones, and in the skull, sternum, and ribs among the flat bones. The bones of the foot and hand are also very frequently affected.

Osteitis is a very common affection, although not much recognized; partly because, from the little attention it has received from our older authors, and from the fact that most swellings of bone are regarded as periosteal, we are not much in the habit of looking for it; and partly because its symptoms are at first obscure, and liable to be masked by those of the injury to the soft parts with which it is associated, or of the constitutional affection from which it springs.

The symptoms vary according to the stage of the inflammation. In the first stage, that in which the size of the vessels is increased, and in which absorption is being produced, the disease frequently makes considerable progress without appreciable symptoms.[1] Sooner or later, however, the occurrence of those characteristic pains in the bones, exacerbated by changes of weather, increasing in severity during the night, and somewhat resembling the pains of rheumatism, which are described by French writers as "douleurs ostéocopes," draw the attention of the patient to the seat of the disease, and form a valuable guide to the surgeon. If the part be now examined, the probability is that some evidence will be found of inflammation in the tissues surrounding the bone—œdema, redness of the skin, tenderness of the soft parts, or threatening abscess. The absorption of the earthy material which accompanies this increased vascularity, manifests its effects upon the bone by a diminution in its consistence, and then the bone becomes at the same time increased in volume and diminished in its resistance to pressure. The former symptom is indeed somewhat delusive, since the apparent increase is often due principally to enlargement of the soft parts. Thus, the expansion of the joint-ends of bones, which frequently appears so considerable in chronic affections of the joints, is often reduced to a hardly appreciable enlargement on dissection. But the swelling of the bone may sometimes be made out very clearly, and is then a valuable indication of the disease. The softening is not generally of much importance as a diagnostic symptom; it rarely affects the whole thickness of a bone, so as to lead to a change in its form, and, when limited to a portion of the surface, cannot be appreciated by the touch, since the inflamed and irritable condition of the soft parts renders the patient unable to bear the necessary pressure.

A singular change, which sometimes follows inflammation of a long bone, is its elongation. Dr. Humphry has laid much stress upon the consequences of diseased conditions of the epiphyseal lines near the ends of long bones, as affecting their subsequent growth.[1] It is possible that inflammation of this tissue may have led to the elongation of the bone in some of the cases; as in a tibia from a lad aged eighteen, preserved in the Museum of St. Bartholomew's Hospital, in which the bone has become lengthened, and is curved in order to adapt its length to that of the healthy fibula.

[The elongation of bone, as a consequence of inflammation, sometimes leads to errors when, in injuries of the limbs, accurate measurements are required. The history of the case will generally explain any discrepancy which may be found, and should always be appealed to. Another fact which weakens confidence in measurement of the limbs is found in the inequality in length of the limbs of persons in whom no previous accident or disease has existed.

---

[1] This is true more especially of the earlier stages, but is occasionally observed in all periods of inflammation of bone. Thus large psoas abscesses, connected with extensive erosion of the vertebræ, are found sometimes in patients not of a strumous habit, and who have not been known to present any symptoms of such an affection.

[1] Med.-Chir. Trans., vol. xlv., p. 294.

Drs. Cox, Hunt, and Roberts, of Philadelphia, have shown, by careful measurement of large numbers of patients supposed to have perfect limbs, that great inequalities exist in the length of the two limbs; in fact, that perfect equality is rather the exception than the rule. These observations on living persons have been amply confirmed by Dr. J. G. Garson, Anatomy Assistant at the Royal College of Surgeons, London, who has measured the lower limbs of seventy skeletons, and found them equal on the two sides in only about ten per cent. of the whole number examined. The extent of the variation was about an average of 4 mm., not confined to any age, sex, or race.]

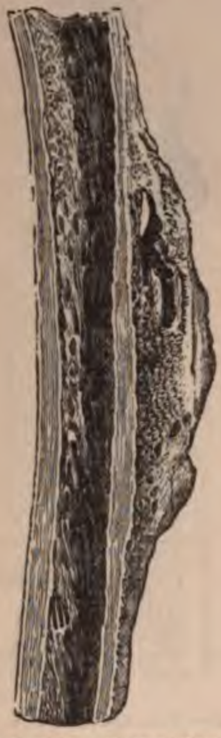
To the stage of absorption and rarefaction succeeds that of effusion and deposit, unless the process be arrested, and resolution occur. The various consequences of suppuration enumerated on p. 121 being reserved for subsequent sections, we need now only consider that termination of inflammation of bone in hardening or sclerosis, which corresponds to the inflammatory solidification of parenchymatous organs; and which, when not too extensive, is for practical purposes little less desirable than complete restoration to health. The interstices of the cancellous tissue are filled up at first with lymph, in which ossific matter is afterwards deposited;[1] and then the bone, which, while actively inflamed, had been less dense than in its healthy condition, as in fig. 570, becomes hard, heavy, and solid, as in fig. 571; the medullary canal is narrowed or filled up, and the shaft thickened by deposit from the periosteum. Bones thus affected abound in every pathological collection; and it is easy to trace in them many of the appearances of which an explanation has been attempted above—the large size of the vascular apertures, the irregular deposit of bone, both in the centre, the substance, and on the surface of the shaft, the contraction of the medullary cavity, and usually the increase in size of the nutrient foramina. It will generally, but not always, be noticed that these changes are limited to the shaft of the bone, when it is the part first affected, and that the articular ends escape. The converse is also usually the case; though perhaps the shaft is more prone to become involved in the morbid actions of the joint-ends than the joint-ends are in those of the shaft. Thus inflammatory affections may long go on in the shaft of the femur, yet the knee-joint remain unaffected; and, on the other hand, where disease of the joint commences in the articular ends of the bones, the shafts usually are unaffected, and the disease of the bones considered by itself is not so extensive as to contraindicate excision. To each of these two general rules, however, numerous exceptions will, unfortunately, be met with in practice.

---

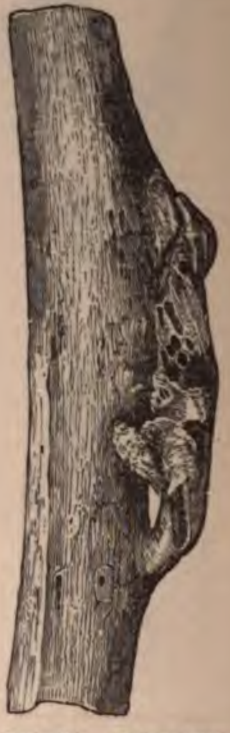
[1] An instructive case is related by Mr. T. Smith, in Path. Soc. Trans., vol. xviii., p. 218, of an amputation in a case of chronic ostitis of the femur. "The shaft of the femur was somewhat enlarged, but its texture was greatly condensed and indurated. The cancellous tissue of the lower end of the bone was plentifully infiltrated with lymph in various stages of disintegration, being apparently purulent about the epiphyseal line.

Fig. 572.



Periostitis. (Internal view.)

Fig. 573.



Periostitis. (External view.)

Two drawings from a preparation in St. George's Hospital Museum, to illustrate the ordinary anatomy of periostitis.

Inflammation of the bone is almost always known, in common parlance (when it is recognized at all), as *periostitis;* but in truth, periostitis seldom occurs uncomplicated, unless in the course of secondary syphilis;[1] and almost all the cases which pass under that name are really inflammations, more or less extensive, of the bone.

[It is generally conceded by writers on

The lymph was especially abundant towards the articular end of the bone, where it extended up to and beneath the articular cartilage, which latter was in parts removed by ulceration."

[1] I would refer the reader to the section on Syphilis in Bone for further details on the subject of chronic periostitis.

this subject that inflammation of a bone is never entirely confined to one or other of its constituent parts, but that it is always an affection of the bone as a complete organ, the inflammatory changes predominating, sometimes in one and sometimes in another of these constituents, and hence the terms osteitis, periostitis, myelitis. Gosselin, in his elaborate article in the Dictionnaire de Médecine et de Chirurgie Pratique, says: "A long observation has taught me that, in pathology, these three parts, the periosteum, the bone, and the medulla, already so closely associated in their functions, are identified (solidaires) one with another, affected by the same morbid causes, and in effect, become diseased simultaneously, though in different degrees." This view of the essential association of the different forms of bone inflammation will serve to throw much light upon difficult questions in bone pathology, and is undoubtedly based upon correct observation; nevertheless in practice it is convenient to recognize both pathological and clinical differences between osteitis, periostitis, and myelitis.

These pathological views are well illustrated by a case reported by Dr. H. B. Sands to the New York Pathological Society in 1871. A healthy boy, nine years old, was attacked with severe pain in his thigh, with some tenderness. This continued for a day or two, then fever developed, the temperature rising to 103.° On the fourth day he was delirious at night, with a pulse of 104 and feeble, the tongue dry, and great constitutional depression. The tenderness had now diffused itself along the whole thigh, deep pressure giving pain. There was no effusion into the knee-joint. There was no apparent swelling of the thigh, and he was able to move it with some freedom. Careful measurement showed the diseased left thigh to be an inch larger than the right. The pain was paroxysmal and very severe. On the fifth day he was much worse, delirium incessant, pulse failing, temperature high. The thigh was now swollen, but not œdematous. He died on the morning of the sixth day.

On post-mortem inspection the thigh measured two inches more than the sound one. The muscles were somewhat infiltrated, but no inflammatory signs appeared till the periosteum was reached. The outer surface of this membrane throughout nearly the entire shaft of the femur was surrounded by pus, accumulated in greatest quantity at a point above and at one below, on the outer aspect of the thigh. The periosteum was the seat of an acute œdema, and separated more readily than it should from the subjacent bone. On raising it from the bone, there were seen some small deposits of pus here and there, lying between the attached surface and the bone; but these deposits were not in so large quantity as those on the external aspect of the membrane, which itself was not at any point perforated. The hip and knee-joints were unaffected. On section of the bone the whole marrow was found to be hyperæmic. In some places it appeared very soft and presented patches of a whitish-yellow color, due to diffluent purulent material. This condition of the medulla extended up to, but not at any point beyond, the epiphyseal line. On microscopic examination the pus-like deposits were found to be mainly composed of closely aggregated small roundish cells, smaller than pus-corpuscles, pale, very finely granular, without nuclei, embedded in an extremely viscid granular substance. The bright-red pulp of the marrow of the shaft presented a much smaller proportion of cells similar to those described, a greater amount of fat and granular matter, and was gorged with blood.

This case shows that in an acute attack of osteitis, lasting only six days, the inflammatory process was nearly equally developed in periosteum and medulla; and leaves the reasonable inference that the bone substance itself was as much and as deeply involved as its structure permitted it to be in the acute processes which surrounded it, illustrating, though perhaps not proving, the pathological oneness of the three constituent structures of the bone.

That inflammation may thus pursue its course more fully developed on the side of the periosteum or of the medulla, is of course perfectly understood. That it does thus go through its chief manifestations in the bone-tissue itself, is a pathological rarity. Of this, however, Lidell gives one case which he presents in elaborate detail, in the concluding of which he says: "The healthy condition of the medulla in this case, and the small amount of disease of the periosteum, show conclusively that this was an instance of primary inflammation of the bone itself." He states that it is the only case of the kind that he has seen.]

That this is so, will hardly be doubted by any one who considers how few preparations of pure periostitis can be found in our museums, and how seldom, during our post-mortem examinations, we meet with periostitis unattended by inflammatory deposit in the deeper parts of the bone. The symptoms, as well as the morbid anatomy, of both are identical, only that in periostitis the thickening and vascularity involves no other part of the nutrient membrane of the bone except the periosteum, and that the inflammatory deposit is confined to the surface of the bone, between it and the periosteum. Periostitis is a quicker process, and one more under the influence of remedies than the other forms of inflammation of bone; but in all the same general course of treatment is indicated, viz., the internal administration of iodide of potassium, and the local application either of iodine or mercurial ointment, or, in the early stage of the disease, of blisters. These measures should be combined with proper position of the affected member, and as much rest as is consistent with attention to the general health. Leeches or cupping will afford relief if the pain be severe. When there is much tension over the bone, sometimes accompanied (especially in the cranium) with intolerable pain, nothing gives such immediate and decided relief as a free and bold incision down to the bone. The distended periosteum is thus relaxed; and in cases of pure periostitis such a measure may of itself almost suffice for the cure of the disease; but its beneficial effects will be decided, though less striking, in cases of deeper-seated inflammation. In cases of chronic inflammation of bone, accompanied by deep-seated and wearing pain, an opening made with a trephine, for the evacuation of pus, has proved beneficial, even though no pus was found.[1]

Whether the sclerosis or induration, which is the final result of chronic inflammation, be amenable to any remedial measures is doubtful, since it usually gives the patient little inconvenience, and therefore is not made the subject of treatment. Thickening over the bone is often left after osteitis, and is often dispersed by the ordinary measures, such as friction and pressure; but the seat of this thickening is very generally in the soft parts around the bone, and not beneath the periosteum.

Diffuse periostitis.—Inflammation of the bony tissue itself is rarely acute, and when it does occur in the acute form passes rapidly into necrosis, under which head it will be presently spoken of; but acute inflammation between the bone and periosteum, *diffuse periostitis*, is a disease of rather frequent occurrence, and is less noticed in surgical works than its importance would seem to require. It is seen commonly enough in persons about the age of puberty; more frequently in boys than in girls; usually as the result of some injury, and almost always in one of the long bones. It is so destructive in its effects, so rapid in its course, and is so little recognized, that we have unfortunately numerous opportunities of verifying its existence after the time for treatment has passed away; yet to early and vigorous treatment it is tolerably amenable, at least as amenable as so acute a disease can be expected to be.

The pathology of the disease appears to consist in the partial separation of the periosteum from the bone, by effusion on the surface of the latter of lymph, or other products,[1] soon giving place to a copious formation of pus, which spreads along the whole bone, and dissects away the periosteum from it, often from one end of the bone to the other. If examined at an early period of the disease, the periosteum does not (at least it very often does not) display any distinct signs of inflammation, either in change of color or of thickness; nor is the surface of the bone visibly inflamed. On the contrary, it usually looks white, and inclined to gangrene, a consummation which rapidly impends over such cases. Sometimes, however, the surface of the bone may be found slightly worm-eaten, and on squeezing it, its superficial layers are found more readily separable from the deeper tissues than in health; large drops of blood can in such instances be pressed out of the vessels which pass into the bone from the periosteum. A little later, and necrosis is unmistakably declared, and the whole diaphysis usually perishes, leaving the articular ends unaffected, and therefore not involving the neighboring joints.

The joint, however, does not always escape. A girl aged fifteen was admitted into hospital four days after an injury, with great swelling of the fore-arm, evidently depending on the formation of matter. A grating sensation, perceived on rotating the hand, together with the history of the accident, led to the belief that fracture had occurred. She died of pyæmia; and then it was discovered that a periosteal abscess, extending from the shaft of the radius into the wrist-joint, had so eroded the articular cartilages as to occasion the sensation of crepitus.

---

[1] See a case reported by Sir B. Brodie, in his Lectures on Pathology and Surgery, p. 410. On the good effects of a free incision of inflamed periosteum, when milder measures fail, see Sir P. Crampton "On Periostitis," Dublin Hospital Reports, vol. i., p. 331.

[1] The disease does not commence by the formation of abscess; often when the swelling and inflammation are considerable, no pus will be found. Of this fact the following is an instance. A lad was suffering from what was supposed to be diffuse cellular inflammation around the ankle after a slight injury. As it was suspected that the inflammation was really subperiosteal, an incision was made down to the tibia. No pus followed. Two days afterwards the boy presented obvious symptoms of confined matter, and now by breaking up the adhesions of the wound a copious evacuation of pus was obtained, and the surface of the bone was felt exposed. A few days later, swelling and tenderness were found over a higher part of the tibia. Thinking that on the former occasion I might not have divided the periosteum freely enough, I now took care to press the edge of the knife firmly against the bone for some distance. Matters went on exactly as in the former wound. No pus was found at the time, but on breaking down adhesions, two days later, with a probe, the pus was discharged, and the bone felt exposed.

The course of the disease is usually as follows: it commences in the great majority of cases with an injury of more or less severity, occurring to a person generally of the strumous constitution, at any rate a weakly person; the symptoms which immediately follow the injury are usually slight, so that even the occurrence of the accident is perhaps nearly forgotten; then, after a varying lapse of time, probably four or five days, symptoms occur which are almost invariably attributed at first to diffuse cellular inflammation, or to acute rheumatism, viz., rigors, pain in the part, and an œdematous angry swelling. At the outset the diagnosis is not easy; indeed, before suppuration has occurred, perhaps no certain diagnosis can be made. However, as respects diffuse cellular inflammation, the age of the patient, the comparative remoteness of the cause, and the previous immunity of the superficial parts, will lead to a suspicion of the nature of the case, which will be strengthened when the inflammation is seen to be limited to the section of the member first affected, instead of passing the joint, and spreading up the limb, as an erysipelatous affection would in all likelihood do, and will be converted into certainty by the discovery of deep-seated matter, either by fluctuation, or on puncture. Fluctuation cannot always be detected, since the tension of the membranes which bind down the pus, and the tenderness of the superficial parts combine to oppose its discovery. Exploratory punctures, however, should never be neglected. If the disease be merely superficial, they can do no harm; and it is of vital importance to discover early, and give instant exit to, the pus before it has dissected off large portions of the periosteum, and involved the death of a great part of the bone. The diagnosis between a case of this sort and one of acute rheumatism will depend upon the nature and history of the disease, and on the presence or absence of constitutional symptoms of rheumatism, or rheumatic affections of remote parts. At the outset of the case the diagnosis may not be very confident; but the main point to recollect is, that any periosteal affection, if acute, is liable to run early into suppuration, and that in such cases, whatever view may be taken of the origin of the disease, whether it is to be considered rheumatic or otherwise, the local treatment is far more important than the constitutional. What Sir P. Crampton says of the acute periosteal whitlow applies with much greater force to acute periosteal affections of the larger bones: "there are few diseases where art can do so much and nature so little."

If the disease be allowed to go on unchecked, the whole circumference of the limb will become greatly swollen and œdematous, usually with that tense glistening aspect which tells of subjacent suppuration. The patient mostly complains of great pain, especially acute at night; he loses appetite and flesh rapidly. Pyæmia is very likely to occur, and many of these patients die of it. A few die exhausted by the violence of the action, and by the profuse suppuration. If the patient survive, and the abscess do not obtain a free and depending opening by timely incisions, it will burrow among the muscles, and ultimately numerous openings will form, exposing necrosed bone. The dead bone appears to separate much sooner than in other forms of necrosis, and the repair to be proportionally active. Thus, in an adult, almost the entire length of the shaft of the ulna was thrown off and removed three months after the injury which led to the complaint; and, even at that date, the repair appeared to be far advanced. In less acute cases, where only a portion of the surface of a bone is involved, the disease pursues the ordinary course of necrosis.

The subjects of this affection are almost always young persons,[1] in whom the strumous diathesis is well pronounced, but it occurs more rarely in healthy subjects about the age of puberty, or even earlier; and some cases are observed (as the one to which allusion has just been made) in adults of impaired constitution and dissipated habits.

The bone affected is, in the great majority of cases, the femur or tibia; and it is no doubt in consequence of the great size of these bones, and the severe effects which always attend upon a large abscess situated below the fascia, that the disease is so fatal. But reference has already been made to two cases in which the bones of the fore-arm were attacked; and any of the long bones may be the seat of the disease, and not unfrequently is so. The flat and irregular bones are more rarely affected; but Sir P. Crampton's case[1] is well known, in which an acute abscess formed beneath the periosteum of the bones of the nose and cranium on both sides. A well-marked instance of acute periosteal abscess of the sternum is described in the Path. Soc. Trans., vol. xv., p. 181, and another less clearly described, but probably of the same nature, in vol. iv., p. 61, of the same series.

---

[1] Chassaignac says that, out of eleven cases, only one had passed the seventeenth year, and was below twenty-one; and one was only eleven months old. In the Path. Soc. Trans., vol. vi., p. 284, a well-marked instance is recorded at the age of eleven days. A circumstance which seems to testify to the effect of a constitutional predisposition is mentioned by Chassaignac, viz., that in some cases several acute periosteal abscesses have been present in the same subject.—Mém. de la Soc. de Chir., vol. iv., pp. 286–87.

The treatment of acute periosteal abscess is a matter of the greatest importance, as it is only by vigorous measures that so rapid and dangerous an affection can be relieved. Among these measures, the first and most important is to make timely and sufficient incisions into the swelling. If doubts exist as to the nature of the swelling, or as to the situation of the pus, they will be settled by the grooved needle; but even if no pus be found, it is better in any case of acute periosteal inflammation, where the pain is great, to make an incision down to the bone in the part to which such pain is referred. In children, it will be advisable to administer chloroform before commencing the examination when the affection is deep-seated.

Periostitis sometimes occurs in a sub-acute form marked by rapid swelling around the bone, and by a certain amount of aching pain, but without the severe constitutional symptoms which accompany the graver disease. Incisions should not be made in these cases, unless the surgeon is sure that matter has already formed. The free application of leeches and local warmth will often obviate suppuration; and many surgeons have much confidence in iodide of potassium in full doses, as a remedy in this sub-acute form of the disease.

During the acute stage of a periosteal abscess, free exit having been obtained for the matter, the patient must be treated on general principles; no special internal treatment is necessary for the affection of the bone. The indications are, to allay pain, to support the strength, and to avoid, if possible, the constitutional affection which leads to pyæmia. The last is the most important of all; patients seldom die of the "surgical fever," so-called, which is usually present; they seldom die of the exhaustion of the discharge; but they die by pyæmia in a large percentage of the cases. How great the mortality is, it would be difficult to say, since the disease is not generally recognized in our hospital nomenclature; but out of a comparatively small number of cases which have occurred during the last few years in the surgical wards of St. George's Hospital, a very large proportion have died of pyæmia. Free and early incisions give the patient the best chance of escaping this fatal complication. No fear need be entertained of decomposition of the pus from the admission of air. In fact, pus which is confined over a bone in an acute inflammatory disease, will probably be already sufficiently putrid. The openings should at first be made in as depending a position as possible, and they should be so free as to preclude all risk of their closing again. After the opening of the abscess, free stimulation is generally, if not always, necessary. The patient will, perhaps, be unable at first to take solid nourishment, since these affections are generally attended with severe fever; but as soon as the evacuation of the matter has removed some part of the irritation, his appetite will probably return.

In abscesses which are at once deeply seated and small, it may sometimes be advisable to use a drainage-tube; but in most cases the collection of matter is too extensive to allow of this treatment being beneficially adopted, at any rate till a later period of the case, when the abscess is contracting and the incisions show a tendency to close. In the memoir of M. Chassaignac, already referred to, the author speaks highly of the advantage of injections of very dilute hydrochloric acid, which have the effect, according to him, not only of cleansing the suppurating cavity, but also of hastening the removal of superficial exfoliations by dissolving the dead bone.

If the patient has survived the acute stage of the disease, the abscess may long remain in a chronic condition, exposing the bone. In the more favorable cases, the outer shell only of the latter has perished; while in the most severe, the entire shaft, separated from the epiphyses, may come away in a mass; or even the epiphyses themselves may share in the destruction, though that is not often the case. The treatment of these sequelæ of diffuse periostitis will be spoken of in the section on Necrosis, where also will be found discussed the subject of subperiosteal resection for acute disease.

Osteo-myelitis.—Diffuse inflammation, and suppuration, in the cancellous tissue, an affection to which French pathologists have given the name of "osteo-myelitis," is more frequently recognized in post-mortem examinations than at the bedside of the patient. The more acute and more extensive cases of this affection are closely allied to pyæmia, and are usually, or at any rate very frequently, followed by that mode of death. It bears the same relation to the medullary tissue as the complaint just spoken of does to the periosteum; but the difference in character between the periosteum and the medullary tissue, the latter being so much more rich in vessels, especially in large patulous venous channels, gives to osteo-myelitis a gravity even beyond that of diffused periostitis. It is well known how often diffuse suppuration is found in the diploë of the cranium after scalp-wounds, and how the "puffy tumor of Pott" is frequently only the sign of such suppuration; and further, in what a large percentage of such cases evident pyæmia is found. It is probable that in all these cases the external table of the bone has been wounded, and the diploë thus exposed; in fact, the only known cause of osteo-myelitis is a wound which exposes the cancellous interior,[1] or an injury to the interior of the bone, perhaps unaccompanied by external wound, as in fracture. It is a frequent cause of death after amputations and other surgical operations in which bone is divided.

---

[1] Dublin Hospital Reports, loc. cit.

When a bone is examined in which osteo-myelitis has run an acute course, the cancelli are found loaded with pus, and the medullary tissue usually injected and often sprinkled with ecchymoses; the periosteum also is often in the course of separation from the bone; but the bony tissue itself does not generally show any appreciable change. In the larger bones the disease usually terminates fatally at this stage; but should the patient survive, the pus may penetrate into neighboring parts, most probably into the nearest joint, or central necrosis may result.

Specimens to show either of these terminations are not wanting in our pathological collections. Thus, in the Museum of St. Bartholomew's Hospital there is a beautiful specimen[2] of inflamed and thickened medullary membrane of the humerus, which shows, as a consequence of the inflammation, a portion of cancellous tissue exfoliated and lying loose in the medullary canal. A long fistula leads through the tube of the bone into the elbow-joint. The same museum possesses another specimen,[3] in which acute diffused suppuration, spreading through the tissues of many of the long bones, has caused abscess in the knees and ankles on both sides.

The symptoms of this grave affection are exceedingly obscure: it, like other extensive and acute affections of bones, is often accompanied by diffuse inflammation of the soft parts, which then masks the deeper affection. Rigors and general fever always mark the onset of acute osteo-myelitis, but the only known special symptom of the disease in the bone is the separation or recession of the periosteum from it, accompanying diffused pain in the bone, and not caused by effusion on the external surface of the latter. After amputations, a prominent fungous mass is often seen projecting from the end of the bone, and proves the existence of a certain extent of inflammation of the medullary tissue; but this need not necessarily have affected the bone so extensively as to deserve the name of osteo-myelitis; in fact, that affection is seldom recognized before death.[1]

To obviate the formidable dangers, and the extensive disintegration of parts connected with osteo-myelitis, it is justifiable in any case where pain in the bone, accompanied with the ordinary symptoms of acute suppuration (rigors, fever, etc.), but without signs of external or periosteal mischief, induces a reasonable suspicion of this affection, to expose the surface of the bone by a free incision. Should the periosteum be found separated, or even separating, from the bone, the diagnosis of diffused suppuration in the cancelli will be rendered highly probable. When this separation of the periosteum has proceeded to any great extent, amputation of the member, or excision of the diseased bone, is certainly indicated. It should be remembered that the disease is a rapid one, the fatal complications of internal phlebitis and pyæmia imminent; and therefore treatment, to be effectual, must be adopted early. Medicine, as might be expected, has little effect on the disease; but the fever which accompanies it should, of course, be treated on the ordinary principles. In deciding on the question of removing the diseased bone (an operation which would in ordinary cases be held to be contra-indicated if pyæmia had set in), it should not be forgotten how much the early symptoms of systemic infection resemble those of typhoid fever;[1] so that it may be proper in doubtful cases to give the patient the benefit of the doubt, and attempt to relieve him from the source of irritation.

---

[1] Unless the infection of constitutional syphilis should be added. See infra, on Syphilis in Bone.

[2] Series i., No. 207.

[3] Ibid., No. 195. See also No. 104, a preparation in which the whole of the inner portion of the os calcis is separating from its outer wall, as a consequence of diffused suppuration through its cancelli.

[1] If after an amputation acute osteo-myelitis be suspected, the surgeon can establish his diagnosis by putting the patient under chloroform, and ascertaining by means of the probe that the whole medullary tissue is broken up for a considerable distance, as well as the small portion which is projecting out of the wound. See Fayrer, in Indian Annals of Med. Science, Oct., 1865. "The symptoms of acute osteo-myelitis are pain in the part, œdema, and swelling extending down the limb; general fever, with quick pulse, and increased temperature, and more especially the recession of the soft parts, including the periosteum, from the bone, which is then left denuded at the bottom of the wound."—St. George's Hospital Reports, vol. i., p. 156.

In chronic osteo-myelitis the removal of the limb is frequently successful in affording the patient relief from an abiding source of irritation, which will at length otherwise prove fatal; but when this affection is limited to a portion only of the bone, the expectant treatment is indicated, and the patient may recover after the extraction of a sequestrum.[2]

[Demarquay has a paper on Osteo-myelitis in the Archives Générales de Médecine, Sept., 1872, which is chiefly devoted to showing the close connection between this disease and pyæmia, and its allied conditions of systemic poisoning. Dr. H. Allen, Am. Journ. of Med. Sciences, Jan., 1865, shows from a careful study of a considerable number of cases that osteo-myelitis is not unfrequently the result of wounds where no bone has been injured, and also that this disease often exists when no symptom has announced its presence during life.

Dr. John A. Lidell, of New York, gives a very complete account of this disease, founded upon his large experience during the War of the Rebellion. After a sketch of the anatomy of bone, in which he emphasizes the fact that the common notion of an endosteal membrane corresponding to the periosteum is erroneous, and that the medulla is a homogeneous substance filling and in direct contact with the bone cavities, he goes on to divide the disease into two forms, the acute and the chronic. The acute is characterized by a sudden pain or aching in the bone, followed quickly by great constitutional disturbance, rapidly failing strength, and often death, within a few days, from asthenia. The causes of this formidable disease are, first, and most important, that peculiar combination of unfavorable circumstances which we call hospitalism, and which surely develops itself when large numbers of wounded men are crowded together. Secondly, this first great cause acts chiefly upon open wounds of bone, as compound fractures, amputations in continuity, etc. Concussion and contusion of bone may sometimes give rise to the affection when no open wound exists. The lodgment of a foreign body, particularly in the medullary cavity, syphilis, scrofula, and scurvy, all favor its occurrence, and the painful jolting and bruising which accompanies transportation is believed very often to light up the disease in injuries which might otherwise have escaped.

The symptoms of osteo-myelitis are:—

I. Pain, generally severe, accompanied by deep aching, which continues day and night, often with a feeling as if the bone were being broken or crushed. This pain is not relieved by incisions through the periosteum.

II. Local heat, which is not stated to attain any remarkable degree by the thermometer, and which is soon followed by

III. Swelling of the soft parts around the bone which is the seat of the disease. This swelling is a firm brawny-feeling œdema, which pits upon pressure, and often presents a well-defined and abrupt edge, which seems to mark the extent to which the bone inflammation has reached, and when well marked is considered a diagnostic sign of great value.

IV. Some redness is observed on the surface of the diseased region, though this sign is sometimes absent.

V. The pus becomes thin, acrid, sanious, and mixed with oil globules in abundance. If the discharge had become abundant before the disease commenced it is noticed that it rapidly diminishes in quantity and often ceases altogether. As the disease advances, the ill-conditioned discharge again becomes profuse, and has a fetid or putrid odor.

VI. If the opening into the medullary canal is visible, there can often be seen protruding from it a mushroom-shaped growth of granulations, which increase very rapidly and soon break down into a gangrenous detritus.

VII. The periosteum peels very easily from the neighboring bone-surfaces, and seems to be separated from them either by a layer of pus or of fibrinous exudation about to break down into pus. The diagnosis is not difficult when the injured bone can be easily inspected, but is often exceedingly obscure when the diseased part is concealed from view.

With the local signs above described, the general signs of constitutional irritation are early and strongly developed. Fever, rather of an asthenic type, with delirium, stupor, rapid failure of heart power, and utter prostration of muscular strength, sometimes hurry on to death within a few hours of the commencement of the disease, or instead of thus suddenly overwhelming the powers of life, they may be prolonged and merge into the more characteristic signs of pyæmia or septicæmia, with which the fatal cases are almost uniformly complicated.

---

[1] See vol. i., p. 546.

[2] I would refer on the subject of chronic and acute osteo-myelitis, to the well-known paper by M. J. Roux, read before the Académie Imp. de Méd., and to the criticisms of M. Legouest, M. Larrey, and others on it, which are to found in the Society's Bulletin for 1859–60, vol. xxv.; to a paper by Mr. Longmore, in Med.-Chir. Trans., vol. xlviii.; and to one by myself, in St. George's Hospital Reports, vol. i., quoted above.

The pathological anatomy of osteo-myelitis presents three distinct stages, spoken of as carnification or hepatization, suppuration, and gangrene.

1st. The stage of carnification shows the marrow of a bone more deeply red than normal, and decidedly increased in the solidity of its feel. The increased color is due partly to a rapid formation of new marrow cells, which displace the fat, and partly to the increase in size of the vessels of the part which send a larger amount of blood into its tissue. From these dilated vessels we have the extravasations of blood which are often seen to stud the medulla as it were with a series of medullary apoplexies. The increased density is explained by the formation of fibrous tissue through the affected medulla, or perhaps also by the sclerosis of the intercellular substance. In some prolonged and less severe cases, a certain amount of bony deposit takes place, sometimes almost filling the medullary cavity.

2d. The stage of suppuration very much resembles the second stage of pneumonia. The red and indurated medulla becomes softened and of a yellowish color. This is due to the gradual transformation of the cells into pus, which at first infiltrates the tissues irregularly, then begins to collect into small purulent foci, which by their coalescence form abscesses. "These in their turn extend, and destroying more or less completely the medullary substance, fill the bone-cavities with pus, the pus now being found in direct contact with the denuded bone-tissue. This exposure is followed almost of necessity by a necrosis, the consequences of which are so serious that the original disease is sometimes lost sight of in view of the disasters which, perhaps, have followed at a considerable interval the earlier signs of osteo-myelitis.

3d. The last stage in the pathological changes in this disease is gangrene of the medulla. This is not a common termination of the affection, it belongs to the most acute and severe cases, and probably would be most often found in patients who have been already depressed by exposure to unfavorable hygienic surroundings. In these cases the marrow is found to have undergone a change of color from the red or yellow to a brownish black; the tissue is entirely broken down, and hangs from the openings in the form of shreds of putrid detritus. The whole medulla may rapidly give way to this fatal change, and of course we should have here a cause of necrosis more potent than mere suppuration, however extensive.

Osteo-myelitis sometimes terminates in recovery. Most recent writers, Pirogoff in particular, recognize this fact. It seems to be the less acute cases, and those which with a short acute stage merge into the sub-acute and chronic conditions which offer most chances of recovery. The severe and acute cases are almost uniformly fatal. It has already been stated that necrosis may be produced when destruction of medulla has largely occurred. This necrosis is of the kind which is termed central, involving the inner lamella of the bone looking toward the medullary cavity, and forming a tubular sequestrum which is imprisoned in the thickened and vascular bone-tissue which surrounds it. That this disease is sometimes the cause of these tubular sequestra cannot be questioned. That it is usually such a cause may I think be doubted. I feel quite sure that such tubular sequestra are commonly produced in a very different way, and are in the majority of instances entirely independent of precedent osteo-myelitis (see note in chapter on necrosis).

As a consequence of osteo-myelitis we may also have osteoporosis and caries, and in a certain number (about one in ten) the morbid action extends to the nearest joint, producing severe, often destructive arthritis. There seems to be also an unexplained tendency to thrombosis of the veins leading from the inflamed region. About 14 per cent. of the cases observed by Dr. Lidell showed this peculiarity more or less distinctly, and in about 35 per cent. of the whole number of cases pyæmia was developed. All the pyæmic cases died. Of all his cases, fifty-one in number, thirty proved fatal.

In speaking of treatment, Dr. Lidell very justly places the hygienic care of the patient in the foremost place. Everything that can be done to distribute wounded men, and to give them the purest possible atmosphere, tends directly to prevent the disease, and to increase the proportion of cures; with regard to medicinal treatment and topical management, nothing very new is advanced. In respect to operative treatment, free incisions down to the bone are advised in suitable cases, and where there is indication that matter is pent up in the medullary cavity trephining is recommended. Dr. Lidell recommends amputation in the sub-acute and chronic forms, as more likely to save life than when the operation is performed in acute cases. He brings evidence to show that amputation in continuity is a dangerous and uncertain procedure, and recommends that disarticulation should always have a preference over any section of the diseased bone, however localized the inflammation of the marrow may be supposed to be.

The association of this formidable disease with pyæmia is so frequent and so close that some have regarded them as identical. This erroneous view has doubtless been suggested by the fact that most of the fatal cases are accompanied by phlebitis of the neighboring veins, the larger trunks being involved as well as the smaller vessels in the immediate vicinity of the disease. This phlebitis partakes of the ill behavior of the bone inflammation, the veins being found distended with a plastic fibrin often putrid, or with an equal quantity of ill-conditioned pus. That this phlebitis is an essential feature of osteomyelitis has not been proved.]

Chronic abscess.—Limited suppuration, or abscess in the cancellous tissue, is an affection which is fortunately far more easily recognized, and far more under the control of surgery, than osteo-myelitis. It hardly needs to be said that this condition of bone was first discovered and described by Sir B. Brodie.[1] The symptoms are not always very clear, but a careful study of the case seldom fails to establish the correct diagnosis. The seat of the disease is almost always the articular extremity of the bones which form one of the great joints,—knee, ankle, or elbow. The tibia is more frequently affected than any other bone, and usually at its upper end. Chronic abscess may, however, occur in any situation.[2] The abscess is almost always situated on the superficial side of the bone, and is probably occasioned, in most cases, by external violence, or other causes, acting on that surface; but the history is often obscure, in consequence of the chronic nature and insidious progress of the malady. The disease is said to be more frequent in England than on the continent of Europe.[3]

The symptoms are, a dull aching pain in the part, often worse at night than during the day, liable also to other remissions and exacerbations, and increased by exercise or pressure. In most cases the bone is especially tender at one particular spot, where the abscess has advanced nearest to the surface, and there is slight tumefaction of the soft parts over it. Sometimes, but not always, a little enlargement of the bone itself may be made out. There is perhaps nothing very characteristic in these symptoms taken separately, or on a first examination; but the persistence of the whole assemblage of them for a considerable period of time, and in spite of judicious treatment, directed to subdue an inflamed condition of the bone, will be reasonable ground for the diagnosis of chronic abscess, and more especially if the neighboring joint be unaffected. The localized, and very circumscribed, tenderness is perhaps, when well marked, the most unmistakable symptom.

The condition of the diseased bone testifies very clearly to the nature of the morbid process, so that few museums are without some of these preparations. The following is Sir B. Brodie's description of the first preparation which he dissected:[1] "The lower end of the tibia is enlarged, and the surface presents marks of great vascularity. The bone in the preparation is divided longitudinally, and just above the articulating surface there is a cavity as large as a small chestnut. This cavity was filled with dark-colored pus. The inner surface of it is smooth. The bone immediately surrounding it is harder than natural."

If the case be allowed to proceed beyond this stage, serious and frequently fatal mischief may ensue from the extension of the abscess into the neighboring joint. Before this event occurs, however, the patient may be much inconvenienced by repeated attacks of swelling and pain in the joints when he attempts to use the limb, the effects of slight synovial inflammation set up by the neighboring abscess. Rest and cold applications will generally remove these symptoms, but only to recur as soon as the patient again attempts to move about. On the cure of the abscess they will immediately and permanently disappear. When the abscess has burst into the joint the affection of the bone becomes merged into the more serious injury to the articulation.

[The chronic disease thus described is perhaps the most common form of bone abscess, but a certain number of cases present some features entirely differing from those above described. These cases are at the onset acute, and suppuration takes place rapidly, with great local suffering and severe constitutional disturbance. The pus very soon perforates the compact tissue enclosing it, and is discharged on the surface, to the temporary relief, but not to the permanent improvement of the condition of the part. The opening not being free, and perhaps not direct, accumulations take place, provoking fresh inflammation, increasing suppurative activity, involving new portions of the cancellous structure, and opening at new points on the surface, and in this way a disease acute in its essential elements, by frequent repetition, leaves a condition of chronic disorganization which I have ventured to term "Chronic Sinuous Abscess." This disease, when it has existed for a long period and after many attacks of inflammation and suppuration, may cease to show any signs of active inflammation, and leave the part in a condition in which it is perforated by three, four, or more sinuses, generally all communicating with one another through a central cavity or chamber which marks the position of the original abscess. From these cavities is discharged a little thinnish pus varying somewhat in amount and appearance. In these cases it would seem as if active disease had ceased because the cancellous tissue was all used up in the morbid processes, or had become so much consolidated by frequent attacks as to be no longer prone to take on inflammatory action. In this condition the disease may last for years, the diseased bone becoming a purely local disorder, not influencing the general health, and not itself showing any disposition towards either extension or cure. The use of the limb may be measurably regained, and thus the patients are sometimes willing to endure, for an indefinite period, a complaint which only occasionally inflicts severe suffering upon them, and which their long experience with the disease has taught them to regard without apprehension. Two of my cases had lasted, one 15 and the other 16 years at the time of operation, a longevity which certainly argues badly for any hope of spontaneous cure. The reason of this unusual obstinacy is doubtless to be found in the indirect and therefore imperfect evacuation of the contents of the cavities, the sluggish character of the actions after the acute stage has subsided, and the unyielding character of the abscess walls, which permits no approximation of the granulating surfaces to one another. This local explanation of the intractability of these cases seems confirmed by the fact that there is usually no general condition on which they may be supposed to depend. The patients are mostly vigorous young persons in whom no syphilitic, strumous, or other constitutional vice can be detected, and in whom local actions would be likely to be healthful and reparative; and it is still further strengthened when we notice that, although the persevering use of internal remedies produces no appreciable good effect, yet the moment the local conditions are improved by appropriate operation, healthy repair begins and goes on rapidly to a sound and permanent cure. A single case will illustrate the disease sufficiently.

---

[3] Mr. A. Bruce, in Med. Times and Gazette, 1868, vol. i., p. 297.

[1] Op. cit., p. 397. The original preparation is in the Museum of St. George's Hospital, series ii., 30.

G. B., æt. 19, entered the N. Y. Hospital in Nov., 1857, with a diseased condition of left tibia, dating about 14 months previously. He was recovering from what seemed a rheumatic attack, caused by exposure, when a sudden inflammation seized the lower part of his leg. He was confined to bed with great pain and high fever. An abscess formed in about three weeks, which broke on the anterior surface of the leg, about four inches above the ankle. The swelling and inflammation continued, and, during five months, he was scarcely able to leave his bed except on crutches. During this time, abscesses formed and broke at several points of the swollen limb, and at various times ten or twelve minute pieces of bone came away. For the last few months the acuter symptoms have subsided, and he has been able to go about, though with much discomfort. On examination the lower third of the tibia was enlarged to twice its natural size. Over it the tissues were thickened and brawny, and the skin presented several orifices of sinuses, which led down into the substance of the bone and discharged a moderate quantity of pus. The probe passed in at any of these openings goes deeply into the bone, and encounters some rough bony points, but no sequestrum. The ankle-joint is swollen and rigid for some months. His general condition excellent. No syphilis. An operation was performed by Dr. Van Buren soon after his admission, as, from the proximity of the disease to the ankle-joint, delay seemed dangerous. By the trephine and chisel the whole anterior wall of the cavity was removed and every sinus freely exposed. They were all found to communicate with a central cavity as large as a hickory-nut, which lay so near the ankle-joint that there appeared to be merely a thin shell of bone between it and the cavity of the joint. The sinuses which opened on the anterior surface of the bone were entirely exposed by removing their bony covering. Two sinuses, however, penetrated the bone so deeply and had their orifices so far back that they were left. All the cavities were lined by a smooth, soft, reddish, and very vascular membrane, composed of abundant firm granulation-substance, pretty fully organized. Through this membrane the bone tissue could be felt, but it was nowhere extensively exposed, and was apparently healthy. No sequestrum was found. The wound was lightly dressed from the bottom with lint. Everything went on favorably. Sound granulation began almost at once, and rapidly filled up the large chasm left by the operation. As healing progressed, it was noticed that the two sinuses which had penetrated the bone were also closed. His cure was rapid, and was complete when he left the hospital.]

Treatment.—In all cases, as soon as the diagnosis has been so far settled as to satisfy the surgeon that operative interference is justifiable, he ought to explain the nature of the case to the patient, and endeavor to obtain his consent to the simple operation which will at once establish the diagnosis and cure the disease. There is not generally much difficulty in obtaining the consent of the patient, whom long-continued suffering and enforced inactivity have rendered greedy of any chance of relief. Chloroform should be administered, and the suspected part of the bone well exposed by a crucial incision. The bone should then be perforated to a considerable depth with a small trephine, which should not have a shoulder. If one spot on the surface of the bone appears softer than another, this should be selected for the centre of the opening. Very often pus will be seen welling up in the groove, as soon as the trephine has penetrated the compact wall of the bone. The instrument may then be withdrawn, and on the circle of bone being raised with an elevator, the pus will be evacuated. The cavity exposed is lined with a thick "pyogenic" membrane, and its surface is very sensitive. The pus is only in small quantity (generally about a teaspoonful) ;[1] but its evacuation suffices at once to relieve the patient of his wearing pain, and he is soon restored to perfect health, the cavity being filled up with a fibrous material, by which in all probability the excised piece of bone is ultimately reproduced.

Two things may interfere with the complete and immediate success of this operation—the diagnosis may have been correct, but the place selected for trephining may have been not quite the right one; or the diagnosis may have been wrong, and the symptoms have depended merely on chronic ostitis. In the latter case, as may be seen by Sir B. Brodie's patient above referred to (p. 126, note), the operation will often do good, will relieve the pain of the inflammation, and perhaps prove the starting-point of a healthier action. It is well, however, remembering that this mistake has been committed by the best surgeons, to prepare the patient for it, so that he may not be too much disappointed if the surgeon shall afterwards have to confess that no pus was found. If, however, the trephine do not come down upon an abscess, it should not be forgotten that this may depend on the opening having been made on one side of the abscess, which may be lying close to the trephine-hole, but separated from it by a thin bony septum. This is illustrated by the accompanying drawing from a preparation in the Museum of St. George's Hospital. It is advisable, therefore, when the pus has been missed, before giving up the operation, to pierce the walls of the trephine-hole in several directions with a sharp-pointed instrument, in order to remove the bone freely with a chisel if a drop of pus follow any of these punctures.

(From a preparation in St. George's Hospital Museum. Series ii., No. 31.)

Caries.—The word caries will be used in the sequel as equivalent to the term "ulceration of bone." It is true that some pathologists of the greatest authority have limited the use of the term caries to scrofulous ulceration, and others have sought to establish a generic difference between caries and ulceration. As to the latter point, however, I must confess that a careful perusal of works in which caries and ulceration are treated of under separate heads, has failed to make me see the distinction which the writers wished to establish; and with reference to the former, although there is as much difference between strumous ulceration and simple ulceration, when occurring in a bone, as there is between the same processes in soft parts, I cannot see that there is any more reason to attach a special name to the process as occurring in bones than in other tissues, while confusion is certainly occasioned by the use of a special term in many cases where the strumous nature of the process is only a matter of inference.

---

[1] In an abscess of the lower end of the tibia, after an old gunshot wound, lately under my care, there was at least half an ounce of pus. This was, I think, the largest cavity I have ever met with.

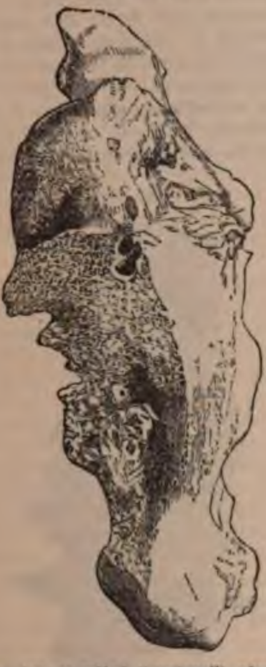
Fig. 576.



Strumous (or so-called "carious") ulceration of bone. (Museum of Royal College of Surgeons. No. 625.)

[The view which regards caries as essentially an ulcerative process has given place of late years to that which regards it as primarily a chronic form of inflammation, with a tendency to infiltrated suppuration and to gradual destruction and removal of bone tissue. Billroth says: "Caries is actually only a chronic inflammation of the connective tissue of the bone with consumption of the latter;" and again, "Perhaps it would be better to gradually drop the name caries and replace it by osteitis, with varying additions, such as rarefying, osteoplastic, ulcerating, granular, etc." This view has been accepted by the principal German pathologists; and Rindfleisch has made a very careful study of the mode in which the destruction is carried on. He has proved that while the lime salts and the basis substance of the bone do at times seem to disappear simultaneously, yet, in a certain very large proportion of cases, the lime salts are first dissolved out, leaving the basis substance as it appears when bone has been soaked in acid; and that as a secondary process this basement substance itself begins to disappear. By the repetition of these destructive actions, large districts of bone disappear, leaving cavities which are spoken of as carious ulceration. It must be clear that this destructive action should be regarded not as the essential, but as an accidental feature of a process which may possibly exist for many weeks without any ulceration whatever. Virchow defines it as a degenerative osteitis; and Stanley, writing forty years ago, says: "I propose here to express by the term caries the changes which, under certain circumstances, are consequent on chronic suppuration in the cancellous texture of bone."]

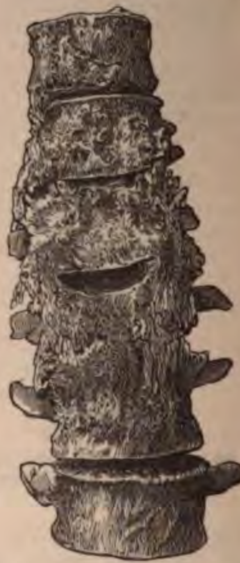
Superficial ulceration is distinguished by the following characters. The periosteum is loosened from the surface, and, if the disease is advanced, will be found much thickened, and converted into a villous mass of a pink color, resembling a layer of granulations. This substance adheres very loosely to the surface of the bone, and when lifted up from it, it is found to fit into depressions, which seem to have been hollowed out of the bone by the agency of the granulations. The bone at a very slight depth underneath is found, in most cases of healthy inflammation, of the ordinary consistence of cancellous tissue, which it resembles in structure even in those parts which ought to be compact. In strumous caries, on the contrary, the osseous structure will be found softened and otherwise altered, as will be described when treating of struma in bone; and it is to this combination of strumous inflammation of the body of a bone with ulceration of its surface, that the old descriptions of caries appear to be intended to apply. The ulcerated surface in healthy inflammation is superficially excavated, much softened, and easily broken down by the pressure of a probe. The interior of carious bone is softened by inflammation, its cancelli enlarged, and filled with the products of the softening and disintegration which have been going on around them. These products, as has been noticed above, are principally oil-globules, blood, and other débris of the soft tissues, and granular inorganic materials, having the same chemical composition as the salts of the bone. The soft tissues almost always take part in the morbid actions which lead to caries, and abscesses are formed which burst externally, and leave sinuses communicating more or less directly with the softened bone, and through which some part of its exposed surface can generally be felt with a probe. Abscesses, however, frequently form in the neighborhood of inflamed bones without any actual communication with them. This is, perhaps, more peculiarly the case in childhood, and near the joints.

Symptoms.—The symptoms of caries are merely those of inflammation *plus* an abscess exposing softened bone; hence all that has been said about the frequent obscurity of the early stages of osteitis will apply to caries, and with greater force, inasmuch as these ulcerative actions are more prone to occur in the course of low inflammations. Constant pain, then, in the neighborhood of a bone, with swelling and more or less loss of the function of the part, followed by abscess which will not heal, indicate usually that the abscess proceeds from ulceration of a bone; and this presumption is much strengthened if the pus have a putrefied, offensive odor, and a prominent mass of granulations project from the sinus; and it is converted into certainty if fragments of bone can be found in the discharge, or if the communication with the bone is sufficiently direct to allow of its being struck with a probe. When carious bone is touched by the probe, it is not usually found particularly sensitive, perhaps is not sensitive at all; it bleeds readily; its surface is irregular, and may generally be felt to be soft. When the opening is sinuous and the bone cannot therefore be struck, the diagnosis can be, of course, only inferential, and founded mainly on the persistence of the symptoms. Chemical analysis of the pus may also sometimes assist the diagnosis, since the pus from diseased bone contains more phosphate of lime than that from soft parts.[1] Sometimes the patient's sensations afford valuable evidence, more particularly in caries from healthy inflammation, where striking lightly over the carious part often causes the same kind of sharp pain as is felt when a carious tooth is struck.

Caries is generally accompanied by more or less of plastic or organizable effusion in the bone in the neighborhood of the ulcerated spot, leading to condensation of the deeper parts of the bone, and to periosteal deposit of bone on the surface. This, however, is the case only in those instances where the process partakes of the healthy or sthenic character. In those low inflammations which are usually called strumous, whether connected with obvious deposit of tubercle or not, such thickening or periosteal deposit is often absent; but the bone is softened throughout all the affected portion, the disintegration becoming less and less perceptible at a distance from the part where the loss of substance exists. The deposit around ulcerated bone frequently leads to anchylosis of the less movable joints; an occurrence which is extremely common in the tarsus.

[The bony deposits which take place at the periphery of the most actively diseased districts may be fairly taken to represent the attempt on the part of nature to repair at least some part of the mischief which has been going on at the diseased centre, and is, at the same time, so constant in its occurrence as to seem an essential feature in the carious process. The true conservative character of these deposits will appear when we reflect that it is precisely in those cases which make the most favorable progress toward a cure, that this osteo-plastic deposition solidifies and reproduces the parts which have been destroyed, and thus renders the damaged bone capable of fulfilling some at least of its original functions. Even those distant and peripheral formations, which seem to have so little connection with the central disease, are seen to have a conservative meaning, when from them arise

Fig. 577.



Caries of the vertebræ; the column supported by ossific deposits.

---

[1] Bransby Cooper, Lectures on Surgery; Barwell, On Diseases of the Joints, p. 238, 1861.

those curious and beautiful bridges and buttresses of bone which spring from one diseased vertebra to another, spanning a chasm of carious destruction of two or three or more vertebræ, and sustaining the column in its tendency to forward displacement where no consolidation of the ulcerated bodies themselves could have afforded the needed firmness (fig. 577).

But while this osteo-plastic tendency is generally recognized as an essential and conservative part of carious disease, few writers have given much attention to those very peculiar and very characteristic granulations which invariably spring forth at the surfaces of osseous destruction and fill the cavities made by disease with a pale, flabby, fleshy mass which fills the morbid excavations, and often protrudes from the orifices of the fistulæ leading to the surface. Mr. Stanley fully recognizes these imperfect granulations, and seems to regard their formation as one of the regular stages of the disease. Billroth merely alludes to them as spongy granulations, to which he attributes the power of dissolving the bone tissue. May they not also be regarded as conservative in their type, and as representing a reparative disposition, though actual repair may be long and successfully opposed by obstinate and advancing disease?]

In cases of superficial ulceration of bone, the agents for its removal are either the periosteum, when that membrane remains entire, or the granulations which spring from inflamed surrounding parts when the periosteum has been removed.[1] Other cases, however, of ulceration are met with, in which the disease is more deeply seated, and commences in inflammation of the membrane lining the cancelli or medullary cavity, and where, therefore, the agents for the removal of the bone are to be sought in the vessels of this membrane. Such cases as these are very rare. I am able to refer to preparations showing the reality of the affection,[2] but I have no knowledge of the special symptoms which it presents, or the indications, if any, which it furnishes. It is evident that, shut up as the inflamed parts are in the interior of the bone, the products of inflammation can find no exit, and the disease must soon become merged in one involving more extensive destruction, *i. e.*, in diffused suppuration or internal necrosis.

A question is very frequently asked as to whether caries or ulceration in bone be a curable affection or not. To this only one answer can be given: viz., that no ulcerative, *i.e.*, destructive, process is ever curable, in the widest sense of that term, since some defect will always remain; but that ulceration in bone, like ulceration in soft parts, may terminate in cicatrization, or the reproduction of an inferior kind of bone which is less vascular, and less smooth and well formed than the portion which it replaces. This fortunate termination becomes less probable, the deeper the disintegration of the bone extends, and the more profound is the constitutional cachexia with which it is associated. In extensive strumous caries it is hopeless.

The *treatment* of bone affected with this form of inflammation is a matter of great importance; since upon the success or failure of such treatment, the preservation of the bone, and with it sometimes of the limb, or even of the life of the patient, may depend. Ulceration in bone does not differ materially from the same process in soft parts, except in the far greater length of time which it usually occupies. In the bone, as in soft parts, the powers of nature will in most cases suffice for cure, when cure is possible, if the parts be put in a suitable position, kept at rest, and preserved clean and free from the accumulation of the discharges.

[If the pathological view be correct which regards caries as a chronic inflammation, then the earliest stages of this inflammation must offer a most important opportunity for successful treatment. There are certain cases in which the early stages are marked by some degree of acuteness and activity. In these there is local pain and local heat, early swelling and early impairment of function. In these it is permissible to use local depletion, as by a few leeches, and their careful use is sometimes beneficial in allaying the starting pains which so often disturb the patient's sleep. This is exceptional practice, however, and it should always be remembered, when leeches are applied in such cases, that their too free or too frequent use tends to depress the vital energies of a part that has before it a long and uncertain reparative struggle. After local depletion the use of mercury has been much discussed, most observers agreeing that it has a controlling power in the earlier stages of the disease. Its use is advised after two methods, first as a purgative, and second, as an alterative. As a purgative, it operates very much as we see it do in certain cases of strumous ophthalmia, where a single dose will sometimes diminish inflammation, relieve the photophobia, and banish pain, which before was intolerable. So sometimes an occasional dose of calomel will act so kindly on the pain and soreness of a commencing caries that we cannot doubt its beneficial action. The alterative method of introducing mercury slowly and carefully into the system is believed by many good practical men to have more power in controlling the inflammatory actions in the earlier stages of this disease, and thereby at least limiting the future destructive tendencies of the disorder. In both modes of using mercury, great care should be taken against overaction of the drug, too free catharsis or any degree of salivation, both being inimical to vigorous repair. In some of the more chronic cases, the bichloride given in very small doses combined with some bitter tonic seems to exercise a favorable influence.

[2] St. Bartholomew's Hospital Museum, series I., No. 163.

During all the earlier stages of caries, rest of the affected parts is a prime indication. Most commonly the patient's own feelings induce him to seek rest, because exercise increases his sufferings. From the outset this rest should be insisted on by the surgeon. It should be perfect, constant, and generally will require to be maintained by mechanical arrangements. In this department modern surgery has been fertile. The first advance upon simple immobilization with the starch bandage, or the carved wooden splint, was made by the elastic extension with weight and pulley, especially applicable to the lower extremity, and requiring a long confinement to bed. From this as a beginning have sprung numerous ingenious instruments, which aim to give the necessary rest to the suffering part without confining the patient to bed, or seriously restricting the ordinary activities of the rest of his frame. All these apparatus have two objects in view: First, to immobilize the diseased joint, for caries is nearly always in their close vicinity; and second, to avoid the pressure of the diseased surfaces against one another, which pressure, though a normal stimulant to a healthy joint, is an injurious irritation to one that is diseased.

About these points, there is little difference of opinion; but a much more difficult question presents itself toward the close of those cases which show favorable tendencies, and where, if nothing be done to avoid it, an anchylosis more or less complete is sure to be established. Of course, in the cases that are recovering from extensive arthritic disorganization, all we can hope for and all we should aim at is a firm anchylosis, particularly in the lower extremity. But in all those very numerous cases where the disease has been moderate, the destruction of tissue limited, and the tendency to repair strongly marked, the question when to begin passive motion, and when active exercise may begin to be allowed, becomes a most important one. It is perhaps not possible to lay down rules by which we may be invariably guided in this important decision, but this has been my own experience:

First, I have waited till all abnormal heat and all local tenderness have disappeared, till dead fragments have ceased to be cast off, till the discharge is no longer offensive, and has assumed a healthy appearance, in short till all the signs indicated a confirmed local convalescence, and then I have felt that the time for motion of the part had arrived. In very slight cases, and particularly in children, a carefully guarded permission to use the limb is safe. But in the severer cases something more effective and at the same time more carefully ordered has to be done. Passive motion must be employed, at first by the surgeon's own hand; and it must be persevered in with no little courage, though it may at the moment inflict such serious suffering as to make it hard to believe that the manipulation is either safe or wise. A rule by which this passive motion may be regulated is one which was formulated by the late Dr. Alex. H. Stevens, viz., make as much passive motion at a fixed hour each day as you judge that the case will bear. If the pain and tenderness produced by the movements last more than twenty-four hours, then you have done too much. If, however, the effects have passed away by the same hour of the next day, then you may proceed and carefully increase the amount. No rule should be too blindly followed, but I have found this a good and a safe one in actual practice.]

But often the patient cannot wait for the completion of the natural process, and calls upon the surgeon to deliver him from the chronic malady which has become insupportable. Or, sometimes his health gives way under the protracted discharge; or, after an interval of quiescence, the caries again makes progress, and threatens to involve neighboring bones, and to impair the functions of the whole limb, if not arrested. This is more peculiarly the case in the tarsus, and other "irregular" bones. In the ordinary treatment, then, of caries, no other local measures are required than to provide a free exit for the discharges, and to keep the exposed surface of bone clean. The appropriate constitutional treatment will complete all that art can do to promote recovery, and more active surgical interference is not only useless but hurtful, as it risks doing harm without a reasonable prospect of doing much good. Incisions, however, should not be spared to the utmost extent necessary to keep the discharge free, or perhaps even somewhat beyond this limit. In fact, in all the acuter cases of osteitis, much benefit appears to follow the mere division of the tense structures over the bone. When the surface can be felt exposed and carious, it is still more necessary to have a free discharge; since otherwise, the pus, being confined, may burrow beneath the periosteum, and extend the mischief to the neighboring parts of the bone.[1]

Often after this free exposure of the carious bone, the disease will gradually subside; but when this is not the case, the question occurs, whether it will be proper to attempt to remove the carious surface and expose a more healthy one, either by rasping or gouging the bone, or by the application of the actual cautery; or to modify the diseased action by injections, or by applications to the carious part. The injections which are in use are composed either of iodine or dilute mineral acid. The latter is intended to unite with the base of the phosphatic salts of the bone, and thus to remove its surface by disintegrating successive portions of it. It has been tried, and is strongly recommended by M. Chassaignac;[2] and no objection appears to exist to its employment in suitable cases; but I cannot say that I have found much benefit from its use. The injection of tincture of iodine in the treatment of abscess depending on disease of inaccessible portions of bone (as in psoas and lumbar abscess), has been warmly extolled by M. Boinet.[3] But M. Robert, who has tested the practice by numerous trials, pronounces (what indeed theoretical reasoning would have led us to expect) that M. Boinet "has singularly over-estimated the good effects of iodine,"[4] and from the few trials that I have had the opportunity of making, I believe that M. Robert's estimate of this treatment is very near the truth. The iodine may be used diluted at first, with one or two parts of water; and afterwards the pure tincture (Lond. Phar.) may be used. It is better at first to withdraw as much of the injection as will run out, and cover the opening with a poultice. Numerous injections will be necessary.

In cases of superficial caries of bones which can be exposed without too much injury to the soft parts (of which the tibia and calcaneum are the most familiar examples), it may sometimes be advisable to rasp or gouge away the carious surface of the bone, and endeavor to arrest the further progress of the disease by the application of the actual cautery or strong nitric acid to the surface so exposed; or, if the disease be very superficial, the latter measure may be sufficient, without any preliminary removal of bone.

Mr. Pollock has employed the application to the carious surface of sulphuric acid, at first diluted with an equal bulk of water, and then more and more nearly pure, pencilled on the surface when exposed by turning away the soft parts. The first application dissolves a portion of the exposed bone, and chars and kills the rest of the surface; when this comes away, if more dead or diseased bone is exposed, it can be similarly treated, until a healthy granulating surface is reached. In this way also superficial exfoliations of necrosed bone can be removed. I have witnessed the success of this plan in the hands of my colleague, and can speak also favorably of it from my personal experience.

Another plan, which is applicable also to the treatment of caries in more deeply-seated bones, has been proposed by Dr. Fitzpatrick.[1] He converts the sinuses leading down on to a diseased bone, into a large funnel-shaped opening, by the repeated action of the Vienna paste (potassa cum calce), and having thus brought the diseased bone within reach, he pierces its tissue with a strong knife, trocar, or small trephine, and then freely cauterizes the full extent of the perforation. The cauterization is to be repeated till the whole extent of the disease seems to be removed, and the use of the limb is restored. Necrosis can, according to Dr. Fitzpatrick, be treated in the same way: "the caustic being very freely used, destroying all foul undermined integument, and leaving large clean circular openings, more than an inch in diameter, and extending deeply down into the sequestrum, into contact with which the caustic in stick and powder is to be freely brought." He recommends it also in simple inflammation (a recommendation in which I cannot say that I concur); but not in diffused suppuration. My personal experience of this treatment has been limited, and in one case which seemed peculiarly well suited for the treatment, and where the disease, which was seated in the ankle, was in a perfectly chronic state, the patient died of pyæmia.

These operations should, however, only be performed in cases of evident necessity. We have only too frequent instances of the dangers of all operations on bone, especially of such as involve the exposure of large surfaces of the cancellous tissue, as is generally the case in these gouging or rasping proceedings, which are extremely apt to be followed by diffused inflammation of the interior of the bone (osteo-myelitis) and by pyæmia. Still, if the disease be accompanied with much pain and loss of motion, and the wound show no tendency to heal, the patient is often compelled to have something done for his cure, as otherwise he would lose his means of livelihood; or the surgeon may think it right to interfere in order to arrest the progress of the disease into neighboring organs. The decision of such questions as these must, of course, be left to individual judgment.

---

[1] Some authors teach that pus exercises a solvent power upon the bony tissue itself. This doctrine appears unsupported by direct evidence; and it seems improbable that the bone can be so dissolved while it retains its vitality.

[2] Mém. de la Société de Chirurgie, loc. cit.

[3] Ibid., vol. vii., p. 454.

[4] Robert, Conférences de Clinique chirurgicale, p. 208. Paris, 1860.

[1] See New Syd. Soc. Biennial Retrospect, 1867–8, p. 259.

The application of the actual or potential cautery appears to be less dangerous than cutting operations, and is often successful in superficial caries. It seems less in use than might be expected, considering the many cases of caries limited to one, and that a superficial, bone of the tarsus and metatarsus, which are seen, especially in children. Here, however, and in all situations where a bone can be removed without prejudice to the function of the part, excision is so much more satisfactory when any large part of the bone is involved, that it is, perhaps, not wonderful that the less radical measures are not much in use.

M. Sédillot has proposed a more extensive use of the operation of scooping or gouging carious bone, as a substitute for excision or amputation.[1] His plan contemplates the removal, by the gouge, of the whole bone except a shell of the outer healthy parts, which is left to effect the restoration of the bone. With all due respect for the authority of M. Sédillot, it seems impossible to allow that such a proposal is either useful or safe. There are few cases of extensive and deep-seated caries in which the limits of the disease can be ascertained, and a partial operation is often worse than none at all. Besides, extensive exposure of the interior of a bone is a most hazardous proceeding, and only too often terminates in pyæmia. M. Sédillot, however, is said to have performed his operation thirteen times without any instance of such complication. The further consideration of this question will occupy a portion of the essay on EXCISIONS.

Ulceration in bone is not always of this chronic nature. Mr. Stanley has described[2] some cases of "phagedænic ulceration" of bone which seem to have been connected with the occurrence of rodent or cancroid ulcer[1] in the soft parts; and in diseases more distinctly partaking of the nature of cancer the bones may be destroyed with great rapidity; but here the affection in the bones is only a part of the general disease, and its treatment must depend on the view which may be taken of the latter. Cases of rapidly spreading ulceration do, however, occur, in which the bone alone is affected.

[The peculiar disease which Mr. Stanley calls phagedænic ulceration of bone, and of which he gives in his brief paragraph a photographic picture, seems to have been regarded by him as a simple ulcer of a peculiar character. Of his three cases the features are all strongly suspicious of epithelioma. Unfortunately the history after amputation is not given. The following case, which was under my observation at the New York Hospital, completes the pathological history.

James O'Brien, æt. 32, was admitted Sept. 10, 1854, with an ulcer on the front of the tibia connected with enlargement and disease of the underlying bone. He had injured the part at the age of 12, and it had never perfectly healed. Sometimes it has almost closed, and then broken out again, gradually growing larger as years have passed, and occasionally bleeding quite freely. No bone has been discharged. The surface of the ulcer, half the size of the palm of the hand, irregular and prominent, was formed of large, hard, wart-like granulations, giving issue to a thin fetid pus. The probe, pressed among the granulations, entered half an inch into the substance of the softened bone. His general condition was good. Finding no improvement from treatment, Dr. Buck gouged the whole mass away, going with his chisel down to what seemed healthy bone. This was not followed by any improvement. No healing action occurred, but new granulations like those removed sprang up over the whole wound, and the ulcerating process was actually progressive and his general health rapidly failing, when amputation was performed just below the knee. The lower two-thirds of both bones were found greatly hypertrophied. At the seat of the ulcer there was a loss of substance equal to more than one-third the diameter of the tibia. The bone substance was irregularly excavated, and on the posterior surface gave evidence that the morbid action was extending through its whole thickness. The substance of the bone gave the idea microscopically that it was infiltrated with a material identical in nature with that of which the wart-like granulations were composed. The infiltration involved the skin, and, to some extent, the surrounding muscles. Dr. Jno. T. Metcalfe made the microscopical examination of the tumor, which was composed mainly of cells of various characters. Many were small, round, with well marked and sometimes double nuclei, others large, with branching processes, others spindle-shaped, but among them many large, flat, single nucleated cells, evidently epithelial.

[1] Lancet, Dec. 10, 1859. Sédillot, Sur l'Évidement des Os.

[2] On Diseases of the Bones, p. 65.

[1] See vol. i., p. 375.

The man recovered well from the amputation, but about four months afterwards I saw him with large masses of new growth in the groin, which were breaking down into a sort of fungous ulceration, which was rapidly destroying the surface while the base was being as rapidly increased. True cancerous cachexia was daily deepening. I heard from him occasionally till his death, which took place a few weeks after I saw him. I heard that the autopsy showed large cancerous masses developed in the pelvis and in some of the internal organs, but could get no detailed report.]

Two remarkable instances have been put on record by Mr. Cæsar Hawkins;[1] in one of which the disease was only part of a general strumous affection, but peculiar on account of its extreme rapidity and great extent. The other was a very remarkable instance of removal, by disease, of great part of the skull-cap, and protrusion of the brain through the opening so left; but without the formation of pus. An abscess was found in the brain, but this was connected with violence done to the protruded portion of that organ, and not with the disease in the bones. No distinct proof of the presence of any constitutional cachexia was obtained, nor was the exciting cause of the complaint apparent. Its inflammatory nature was testified by distinct marks both of inflammatory thickening and of inflammatory erosion on the bone in the neighborhood. Therefore the old definition of ulceration as "absorption from inflammation" would strictly apply to this extraordinary case; and we have already seen (see pp. 119, 120) that the formation of pus, though an ordinary, is not an absolutely necessary, feature in ulceration of bone; but it is rarely indeed that so large a portion of bone is removed without the formation of abscess, especially when compact tissue is involved; for the instances of removal of inflamed bone without suppuration, hitherto noted, have occurred almost exclusively in thick cancellous bones, such as the vertebræ and tarsus.

Necrosis, or the death of some considerable portion of a bone, occurs as the consequence of any cause which sufficiently impedes the circulation in the neighborhood. This is precisely analogous to what takes place in the gangrene of soft parts; and as in gangrene the non-vascular parts are most easily affected, and then those which, though vascular, are furthest from the centre of the circulation, and in which the vessels are fewest and smallest, so the frequent occurrence of necrosis of bone is, no doubt, due to the comparatively small quantity of blood which circulates in that tissue, as well as to the inextensible nature of the osseous substance itself, in consequence of which any extravasation or product of inflammation causes pressure directly upon the bloodvessels, or narrowing of the channels for the conveyance of the nutritive plasma.

It is denied by some authors of reputation on this subject that necrosis is ever a consequence of inflammation of bone,[1] and they refer the disease always to periostitis or osteo-myelitis as its cause. But this appears an error in two senses. In the first place, there is no essential difference between periostitis, or osteo-myelitis, and inflammation of bone. The diseases so called are only inflammations in which the part of bone alone affected, or, as is much more common, the part *most* affected, is the external table or the medullary tissue. In the second place, the disease properly called osteitis very frequently induces necrosis, not indeed usually of the inflamed part, but of the parts in its neighborhood. The inflamed part itself does not usually perish, because the final cause of necrosis is the stoppage of the circulation by the obstruction or obliteration of the vascular channels, while the first effect of inflammation is the enlargement of those channels.

[That acute inflammation of bone does produce necrosis is acknowledged by most authors, Gerdy standing almost alone as a representative of the opposite opinion. The mode in which it acts is hardly clearly stated in the text. The inexpansibility of the walls of the Haversian canals will not permit the sudden increase which acute inflammation demands, and hence the corpuscles become crowded in the capillaries, so that first, retardation and afterwards stoppage of the current occurs; and as no relief can be received from the surrounding vessels in which the circulation is for the same mechanical reason and in the same way affected, it follows as a matter of course that the part most inflamed dies by reason of this stagnation of its circulation. This seems to be the explanation of those cases where after acute osteitis involving the whole thickness, and perhaps the whole shaft of the bone, the whole of the inflamed part falls rapidly into the condition of necrosis.]

When the osteitis has reached the stage of exudation, the dilated vascular channels become again narrowed; but the process takes place slowly, and organization, which involves the formation of new vessels, takes place in the exuded material as it is produced. Still, although the event is not a common one, traces of inflammation are seen on sequestra sufficiently often to show that the inflamed part does sometimes die. The same causes, in fact, which produce gangrene in soft parts will occasion the death of a bone; and among them inflammation holds a high place, less on account of its direct effect, *i. e.*, its tendency to produce the death of the part inflamed, than of its indirect consequences, whereby the circulation around the inflamed part is obstructed, and so necrosis of the neighboring parts is induced. Hence in the course of an extensive caries the circulation of some considerable portion of the bone is apt to be destroyed, and then a necrosis or loose piece is found in the middle of the ulcerated part. Such combination of necrosis with caries was called by the old writers dry caries or hard caries.

---

[1] Med.-Chir. Trans., vol. xxxix., p. 285.

[1] Gerdy, Maladies des Organes du Mouvement, p. 217, 1855.

Another very frequent, if it be not the most common, cause of superficial necrosis is the denudation or separation of the periosteum, which occurs as a consequence either of direct injury or of effusion between it and the bone. It is true that large separations, and even extensive destruction of the periosteum may occur without the death of any portion of the bone, and this is indeed common in the bones of the head and face; but the peculiar circulation in the former, and the great vascularity of all parts in the latter region, sufficiently explain this fact. In other parts, it is the more general rule that when the periosteum is destroyed or separated over any considerable portion of a bone, the superficial layers of the latter will perish. This is one reason, among many, why it is important to adjust the soft parts over a bone denuded by violence, in order that they may rapidly adhere to it, and that so fresh vessels may connect the periosteum to the bone before the latter has undergone any irremediable change.

Violence, acting directly upon the bone, is another very frequent cause of necrosis, as is frequently seen in compound fracture, where both the periosteum and the medullary tissue are much damaged, and the bone dies without any proof of previous inflammation having existed. [It must not be overlooked that violence done to bone-tissue causes sometimes its acute inflammation, and from the incapacity of the tissue to undergo the changes induced by such inflammation portions of the injured tissue die.]

The action of cold is often exhibited on the bones as on the soft parts, and the subject will be found treated of under the head of Frost-Bite (Vol. I., p. 362.) In deep burns the bones are also occasionally charred, and they are frequently involved in gangrene of the superficial tissues, from whatever cause it arises. Certain caustic applications are well known as frequent causes of necrosis, of which the superficial exfoliation produced on the surface of the jaw, for the cure of epulis, is a familiar example. To this category belongs also the necrosis of the jaw which is produced by exposure to the fumes of phosphorus.[1] The various constitutional cachexiæ, especially syphilis and struma, are frequent causes of necrosis; but here the affection of the bones is only a variety of the inflammatory process.

The abuse, and even occasionally the moderate use, of mercury is another cause of necrosis. It is quite true that many of the preparations and cases entitled "necrosis from the abuse of mercury" may be explained as having been cases of syphilitic necrosis, in which mercury had merely failed to arrest the disease, and had nothing to do with causing it; but there are too many instances on record of the occurrence of necrosis of the jaw, during the administration of mercury for some disease which had no influence upon the bones, to admit of a doubt that the affection was directly induced by the so-called remedy. Thus, in the Museum of Guy's Hospital (No. 1091) is a sequestrum consisting of two-thirds of the alveolar process of the lower jaw, which is said to be "necrosis induced by the use of mercury for ovarian dropsy." Unfortunately it appears that what is a moderate use of mercury in one person, is equivalent in rare cases of idiosyncrasy to an excessive abuse, so that no practical rule can be laid down; but it is at any rate proper to remember this occasional effect of mercury, particularly when prescribing it for cachectic persons. In the Museum of St. Bartholomew's Hospital is a preparation, in which necrosis of the jaw is attributed to the administration of a few grains of mercury during a fever; but in some fevers necrosis has been frequently observed as a consequence of mere lowering, as it would seem, of the vital powers, without any mercurial cachexia.[2]

[One cause very potent in producing necrosis is long continued exposure to wet and cold, the two causes combined seeming to be more effective than either separately. Thus many cases are recorded when the disease followed long tramping through snow and slush, and where boys have remained long bathing in very cold water. These forms of exposure produce an acute osteitis which terminates in necrosis.]

---

[1] This affection will be found treated of in the essay on SURGICAL DISEASES OF THE TEETH AND GUMS.

[2] See, in the Museum of St. George's Hospital, series ii., Nos. 91, 95, preparations in which both the jaw and the clavicle became necrosed in the same patient during the course of a fever.

It would be idle to attempt an enumeration of all the causes which may lead to the death of bone. The above are the most common, and will be found sufficient for practice. The symptoms and treatment are identical in most of these forms. Some will require special notice hereafter.

When a portion of bone is to die,[1] the first phenomenon is the cessation of circulation in it. This leaves it hard, white, and sonorous when struck. It does not bleed when exposed or cut into, and is insensible. Occasionally, when the dead bone is exposed to the air, and acted on by the presence of putrid pus, its color becomes nearly or quite black; large surfaces of hard, black, necrosed bone are sometimes left exposed by the sloughing of the skin over the tibia. The dead bone at first retains its connection to the bone around, as well as to the periosteum, or whatever part of the nutrient membrane may belong to it; but the presence of a dead part is never long tolerated by the living tissues, and accordingly the processes which are to eliminate it soon become perceptible on both these structures. The periosteum, or medullary membrane, as the case may be, separates from the dead bone and becomes inflamed, a quantity of ossific deposit (more or less, according to various circumstances) is poured out between it and the dead bone, and this deposit soon becomes converted into new bone, forming a sheath over the dead portion, by which the latter is enclosed, or *invaginated*, as the technical term is. The dead part is now called a *sequestrum*, a name only properly applied to it when loose and invaginated, though often incorrectly used of any piece of dead bone. While this sheath is being formed from the membrane coating the dead bone, changes are going on in the living bone to which it was attached. When the latter has been previously diseased (*i. e.*, when the necrosis has been of inflammatory origin), the inflammatory deposit which surrounds the sequestrum softens, pus is formed, and a groove of ulceration is produced at the expense of the circle of inflamed bone which forms the margin of the sequestrum. If the surrounding bone have been previously healthy, the sequestrum acts as an irritant upon it, setting up, first inflammation and thickening to a variable distance, and then ulceration. Thus a groove is traced around the sequestrum; and the formation of this groove is accompanied by suppuration, as has been described above (see p. 122). The pus formed in the neighborhood of the dead part makes its way to the nearest surface, and in so doing interrupts the formation of the periosteal sheath, leaving sinuses, or *cloacæ*, passing through this sheath from the sequestrum to the surface of the body, or sometimes into a neighboring joint or serous cavity. [The occurrence of cases in which suppuration does not occur in connection with necrosis are acknowledged to be rare. Cases, however, in which suppuration is long delayed and slight in quantity are not so infrequent, and these exceptional cases may lead to error, or at least uncertainty in the diagnosis, if due allowance be not given to their possible occurrence.] The presence of such sinuses, leading through the shell of bone to hard, smooth, sonorous bone at the bottom of the cavity, is the distinguishing mark of necrosis. Most of these points are illustrated by the accompanying figure. [See fig. 578, p. 144.]

The formation of the groove between the dead and living bone is a very slow process in the bones of the limbs, requiring generally many months for its completion. It is impossible to lay down any rule as to the time at which a sequestrum may be expected to be found separated from the rest of the bone. In animals, as has been proved by experiments,[1] the process may be completed in a few days. In children it seems to go on sometimes with great rapidity, especially in the bones of the face. On the other hand, instances are not wanting in which half a lifetime may have elapsed, and the process still remain unfinished.

One of these has furnished a preparation in the Museum of St. Bartholomew's Hospital.[2] It is the section of the shaft of a femur, exhibiting in its interior a small fistulous cavity, with necrosis of a small portion of the inner layers of its wall. A groove extends to some depth between the dead and the contiguous living bone. The limb was removed by amputation. The femur had been fractured thirty-five years previous to the amputation; the fracture was followed by abscess in the soft parts, and the formation of a fistulous passage leading to the interior of the bone, which passage remained open during the whole period from the fracture to the removal of the limb.

It may, however, be stated generally, that the more superficial the dead portion is, the more freely it is exposed, and the more violent the action of the cause has been, the more rapidly will it separate (see p. 127).

When the groove is completed, the dead

---

[1] This description refers to the process as it occurs in bone previously healthy.

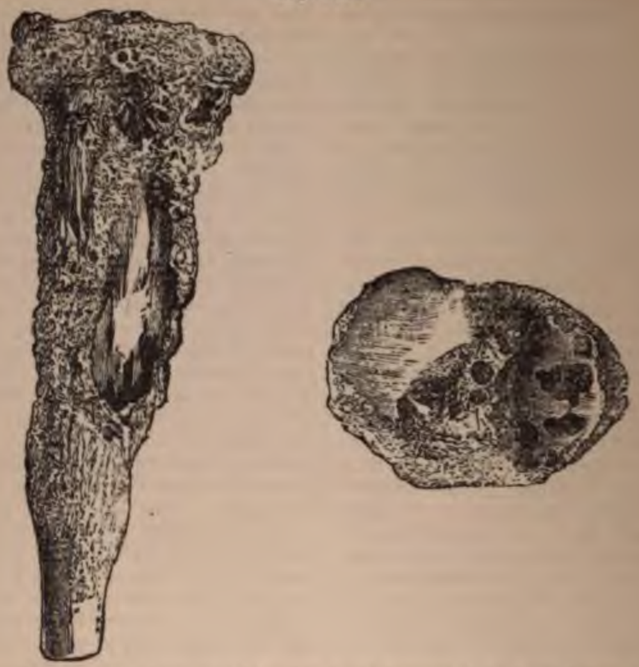
Fig. 578.



From a preparation (No. 3174) of necrosis of the tibia, in the Museum of the Royal College of Surgeons. To show the various points connected with necrosis of a portion of the shaft of a long bone—the sequestrum—its invaginating sheath, formed in a great measure by periosteal deposit, and terminating on the healthy surface of the bone, at some distance from the seat of disease, the openings, or cloacæ, through which the sequestrum is exposed, and (in this instance) the implication of the neighboring joint from the extension of these cloacæ into it.

bone is loose in the cavity so formed for it, and quite free from any vital connection to the body. [This is true in the dried bone, but not in the living patient. During life the surface looking towards the sequestrum is constituted by a layer of granulations, which, surrounding on all sides the dead piece, so support it that no space exists between the two and no motion can take place of the sequestrum in its cavity. In old cases these granulations become very hard and insensible, and form an admirable bed in which the rough and sometimes sharp-edged or sharp-pointed sequestrum often remains without doing harm for many months or even years. This bed of firm granulations explains the fact that the probe does not always detect mobility even long after the separation is complete. In order to elicit the fact that the sequestrum is loose, it is often necessary to press it with a strong steel probe down into the granulations beneath it so as to crush them, and thereby allow some displacement. By repeating this process somewhat forcibly we can soon get the sequestrum to move in its now enlarged enclosure, and appreciate the fact by the probe.] The sequestrum, therefore, is now eliminated, and this may be regarded as the natural process of cure, since it prevents the extension of the necrosis further into the bone; but as the sequestrum is still lodged in its cavity in the interior of the bone, it thus becomes an abiding source of life-long irritation, which must by all means be removed as speedily as possible.

The above is intended for a sketch of the process of necrosis in one of its most frequent seats, viz., the outer (subperiosteal) layers of the compact sheath of a long bone; but it may occur in any situation—in the medullary canal, or central layers of the compact tissue, in flat or irregular bones, or the spongy ends of long bones; or again, the extent of the necrosis, or the situation of the part, may modify considerably the process of separation, *i.e.*, the surgical aspect of the case. For example, even when necrosis is subperiosteal, and the process of separation normal, it may be in a part from which extraction is impossible, as on the inner surface of the skull, spine, pelvis, thorax, etc. The subperiosteal sheath is often wanting in the bones of the limbs when the soft parts have been extensively destroyed over the affected bone; and it is never formed in the skull, where necrosis is so common, nor in the cancellous bones, where, though less common, the disease is by no means rare. In such cases, when the dead bone is loosened from the living, it comes away of itself, or can be at once removed. Such a piece of dead bone, not confined by any invaginating sheath of new bone, is called an *exfoliation*. Again, it sometimes happens that the necrosed portion involves the whole thickness of the shaft of a long bone, and sometimes the whole length of its diaphysis; some instances even are exhibited in the museums where the epiphysis also has perished along with the entire shaft, though this is very rare.[1] Necrosis also sometimes attacks the epiphysis only, and even, as it seems, the deposit of bone which in early life forms the centre of ossification for the epiphysis.[2]

Each of these conditions is accompanied by noticeable peculiarities. When the whole thickness of the shaft is involved, especially in a bone, like the humerus, enjoying free and rapid motion, fracture is likely to follow on the completion of the groove, although this result may be obviated by the strength of the case of new bone. [This, however, is not common, the new bone being usually formed and consolidated before the separating process is complete. Some very interesting cases are recorded of fracture of the involucrum after it had been fully formed. These cases have sometimes been produced by very great and sometimes by very slight degrees of violence, according as the involucrum was strong or weak. The following is a typical instance:—

A. C., a strong and healthy butcher, had had necrosis of shaft of humerus for some years. A large sequestrum lay loose in its involucral cavity, but gave rise to so little inconvenience that he postponed the operation for its removal. On one occasion, in trying to lift a heavy piece of meat to hang it upon a high hook, he felt a sudden snap in his diseased arm, which fell helpless to his side. The bone had broken through the involucrum, and torn its way through the integuments, thus making a bad compound fracture. Between the fragments, in a large cavity, which was now quite exposed, could be seen and felt the sequestrum. This was his state when I saw him in consultation. The first thing to be done was to remove the piece of dead bone, which was easily accomplished, and we had then to deal with a compound fracture in which the ends of the fragments were composed of involucral instead of original bone tissue. The displacement was easily reduced, the broad broken surfaces of the involucrum fitting accurately into one another, and mutually supporting each other. The result was rapid and perfect. He has to-day, twenty-five years after the accident, an arm as strong and as useful as ever it was.]

When the whole diaphysis is involved, the case assumes a graver aspect, since the extent of inflammation which is necessary for the formation of the new shaft, and the great suppuration thereby produced, suspends, or perhaps permanently abolishes, the functions of the limb. The muscles become matted together, the skin œdematous and penetrated by numerous sinuses, the parts below incapable of extended motion or energetic action; cases even are on record where the inflammation, having reached the great vessels, has produced coagulation of the blood in both artery and vein, and consequent dry gangrene of the limb.[1] In other cases either the ulceration around a sequestrum, or other disease of the bone, involves a large vessel, or the point of an exfoliating portion of bone is driven into the artery in some movement of the limb;[2] and thus either a direct wound of the artery is produced (when the sinus of the diseased bone communicates with the laceration in the artery), or if no opening exists externally, a consecutive aneurism may possibly be established.

[Hemorrhages in necrosis are not uncommon, always important, often fatal. They occur sometimes while the patient is taking active exercise, sometimes when he is quiet in bed. They are sometimes slight, with no serious consequences, sometimes they are severe, profuse, and rapidly exhausting. Sometimes they cease spontaneously, sometimes they are uncontrollable by anything short of an operation. As to the slighter forms of hemorrhage, which commonly occur during active exercise, they doubtless depend upon the wounding of the granulations by the sharp edges or points of the sequestrum. Rest and elevation of the limb is all that is required to stop them. The severe cases have features most important to recognize. Thus we may have a sudden profuse gush of blood coming from several of the fistulous openings, with great force, and so rapidly that pallor and faintness are produced before the flow ceases. This may take place without warning, while the patient is asleep in bed. The hemorrhage generally ceases after this first outrush, but recurs again in the same sudden and unexplained manner until a fatal result, either immediate or by gradual sinking, terminates the case. That these cases constitute a formidable group will appear when I state that out of eleven cases which I have myself seen, six have died. These cases mostly occurred in the New York Hospital; in all the gravity of the condition was fully appreciated, and yet only five out of eleven were saved. This happened, too, when everything seemed to be doing well at the time the hemorrhage occurred, and in every case but one the opened vessel was accessible to ligature. The examination of these cases, either after death, amputation, or during operation, revealed the fact that in every one the artery eroded was the principal trunk, except in one instance, and in that case the vertebral was opened near its origin. Several other cases have come to my knowledge since these were tabulated, which raise the whole number to sixteen, bearing the same ratio of mortality, and showing the same pathological condition. The practical deductions from these facts are simple but momentous. The bleeding is from a main trunk, and will be fatal if let alone. The life depends upon promptness, and promptness can only grow out of conviction of danger. The danger is imminent, the remedy not doubtful. Two courses present themselves: either to tie the injured artery at the point wounded, or to amputate the limb. The real risk to the patient is that the surgeon, not fully alive to the real conditions, may wait too long, and not feel convinced of the necessity of operation until it is too late for the operation to save. If possible, the artery should be tied at the wounded point above and below the opening. If not possible to tie the artery at the seat of injury, amputation should be performed at once. A ligature on the trunk immediately above the injured point might prove successful; but it has the great disadvantage that it does not secure against distal hemorrhage, and in my judgment would be rarely successful.

[2] Mr. Poland, in his essay "On Rupture of the Popliteal Artery," quotes one case of spontaneous hemorrhage from that vessel in necrosis of the femur (a patient of Dr. Porter, Dublin Journ., vol. v.), and two others where the artery was wounded by a sequestrum during active movements of the limb (Dr. Byron's case, Med.-Chir. Rev., vol. xxiv., p. 259; Dr. Jacob's Diss. Med.-Chir. de Aneurism. Edin., 1814). I have seen fatal hemorrhage from the lingual artery in disease of the jaw, and from the aorta in caries of the spine. Mr. Stanley (op. cit., p. 111) relates a case in which the capsule of the knee-joint was penetrated by the pointed end of the necrosed shaft of the femur.

Two cases may illustrate the two best modes of treating hemorrhage in necrosis:—

Case I. Martin Clancy, æt. 24, was brought to Bellevue Hospital, Oct. 29, 1869. He was pale and feeble, and said he had had several profuse bleedings from an ulcer in the thigh. These bleedings had occurred suddenly without obvious cause, and each had stopped spontaneously. He was wearing a tourniquet, put on by his outside surgeon. Examination showed necrosis of the shaft of the femur, of which he gave a clear history, dating back nearly seven years. Operation was urgently indicated, and Dr. A. B. Mott immediately performed it. The ordinary operation was first performed by removing the sequestrum through a liberal opening through the involucrum. This was easily accomplished, and a large, flat, sharp-edged sequestrum, evidently formed from the posterior compact substance of the femur just above the condyle, was removed, leaving a large cavity exposed, in which the next step was to search for the eroded artery. After a tedious and extremely difficult and careful search, the opening in the artery was found, from which, on loosening the tourniquet, the blood spurted freely. A ligature was applied above and below the opening, the two ligatures being about an inch apart. The wound was dressed lightly and partly open. Everything went on favorably, and the patient was discharged cured, Dec. 31st, about nine weeks after the operation.

The following case illustrates the second alternative which these cases present, viz., amputation:—

J. McKibbin, a lad of 14, had been under the observation of Dr. Gurdon Buck for several years, during which time the immediate care of the case was taken by Dr. W. W. Jones, of this city. He had had necrosis of the left femur dating back about four years. He had had at several periods slight hemorrhages of dark colored blood, which were easily checked by pressure, and doubtless came from the granulations lining the involucral cavity. He was doing tolerably well, when in August, 1855, after a long walk, he had a considerable bleeding, checked by moderate pressure, but returning again at intervals of several days. On the night of August 31st, while in bed, violent hemorrhage occurred, soaking the bed and cloths which were applied. On September 1st, on removing the bandages, arterial blood again rushed out with great force, requiring instant compression of the femoral above. Under these circumstances of instant peril, no hesitation was felt, and amputation was performed immediately below the trochanter. Examination of the limb showed a long, irregular and sharp-pointed sequestrum, partially extruded from its bed, through a large cloaca, and pressing on the side of the femoral artery, in which a large hole had been eroded by the contact. The opening in the vessel was plugged by a fibrinous coagulum, part of which seemed firm, as if formed some time before the final hemorrhages, and only partly displaced by them.

The specimen is now in the New York Hospital Museum. The boy made a rapid and perfect recovery.

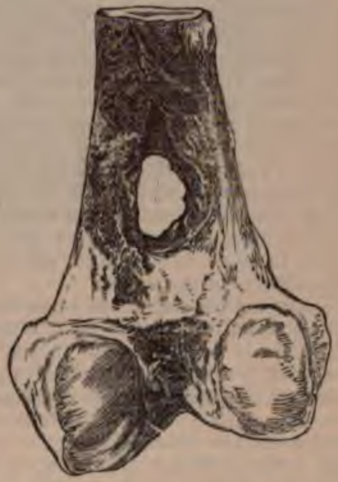
The explanation of these erosions of arteries is to be found in the fact that there is a disposition on the part of these sequestra to be extruded from their involucral imprisonment, and to seek the nearest surface, therein obeying a law which is common to all foreign bodies lodged in the organism. In consequence of this tendency to extrusion, we constantly see sequestra which are not tightly enclosed within a bony case finding their way to the surface, and easily removed. Even those sequestra which are enclosed within the involucrum are sometimes partially extruded through large cloacæ, and thus are brought within the reach of the artery which passes in close proximity. This happened in Dr. Buck's case, above related, and it is strikingly illustrated in a specimen we have in the College Museum. The specimen embraces the femur and tibia above and below the knee-joint, with the femoral and popliteal vessels. The femur shows an old condition of necrosis, with an involucrum, with large cloacæ, from one of which protrudes the end of a sharp and ragged sequestrum, which, emerging in the popliteal space, has caused a large erosion in the popliteal artery. It was taken from the body of a member of our profession, who had several sudden hemorrhages, and before the extreme remedy of amputation was decided on was so reduced that amputation came too late to save his life.

The same pathological view explains the occurrence of some of the most formidable of these hemorrhages when the patient is perfectly quiet, perhaps asleep in bed. The sharp edge of the sequestrum is gradually approaching the artery, by virtue of a force which slowly but steadily brings them together, entirely besides and independent of any muscular movement which may drive them into contact.

Fig. 579 represents the lower end of a femur amputated for hemorrhage from the popliteal artery, which had been opened by a sharp sequestrum from the posterior surface of the bone. The specimen is remarkable from the perforation which has taken place, due to the actions which were going on in the bed from which the sequestrum was obtained. This specimen is in the New York Hospital Museum.]

In any case of such injury to the main vessels, when the diagnosis can be properly established, amputation would be indicated, in the lower limb. In the upper limb the main arteries are separated from the bone by a mass of soft parts; and smaller vessels would hardly complicate the case, as they might be included in the incisions required to expose the diseased bone. In other situations attempts must be made to tie the ulcerated vessel; and if they fail, as they generally will, from the rotten condition of the parts, the trunk leading to it must be secured by ligature or acupressure.

[Fig. 579.



Perforation by a sequestrum. (Specimen in the New York Hospital Museum.)]

In cases of necrosis involving the whole thickness of a bone (*total* necrosis), when the seat of the disease is a large bone, such as the femur, life is in considerable danger; and as the patients are usually persons in whom some constitutional cachexia is present, and probably in an advanced stage, they frequently succumb.[1] Still the dangers of amputation in these cases are so great, and the advantages of saving the limb so decided, that they are usually left to the reparative powers of nature. In small bones, such as the phalanges, amputation is indicated. In the upper limb large portions of the whole thickness of the shaft may be removed with entire success, and preservation of the motions of the extremity. In the essay on EXCISION, the indications for excision of the whole or parts of bones on account of necrosis, involving their whole thickness, will be further considered.

---

[1] An interesting case of total necrosis of the shaft and upper part of the femur in a young subject, aged thirteen, in whom amputation was successfully performed a year and a half after the commencement of the disease, is recorded by Mr. Kerr, of Aberdeen, in the Ed. Med. and Surg. Journ., 1834, vol. xlii., p. 98. It is worth perusing, as showing the activity of repair at that early age.

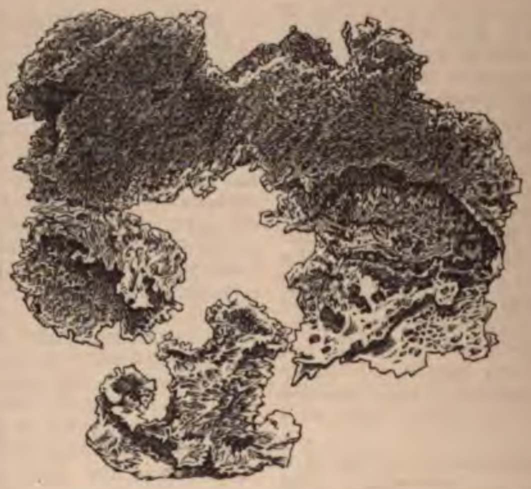
Central necrosis is usually an obscure complaint, and is hardly distinguishable by its symptoms from chronic abscess of the bone. In fact, as their symptoms are the same, so the same treatment is applicable to each of them. Deep-seated pain, throbbing, loss of rest, general debility, perhaps rigors and some amount of fever, with slight puffiness over the seat of the disease, and a little pain on pressure; these symptoms persisting for a considerable period without relief, notwithstanding that the appropriate constitutional and local remedies have been employed, indicate the necessity of making an exploratory incision at the seat of the inflammation, and, if the surface be found healthy, of removing it with the trephine in order to search for an abscess or sequestrum in the centre.

Deep-seated necrosis often leads to suppuration, making its way to a free surface. This is very common in the long bones, and is a frequent cause of abscess and destructive inflammation of the joints. Necrosis may also attack a portion of the articular surface of one of the great joints of the body, although this is rare except as a complication of extensive strumous affection of the joint-surface. Limited necrosis of articular ends is, however, occasionally met with, and, like the previous affection, will set up abscess in the joint. The diagnosis of these causes of articular abscess must be sought in the essay on DISEASES OF THE JOINTS, and the indications for operative treatment in that on EXCISION.

In the flat bones, where they are formed of compact tissue, necrosis is an exceedingly common disease; but here, as has been before observed, the dead bone will usually exfoliate without invagination.

[It should be noted here, however, that although no invagination takes place in these cases of necrosis of the cranial bones, the process of exfoliation is an extremely uncertain one. In fact in many cases of long standing and extensive necrosis of the cranium, no effort at separation can be observed, even when the disease has existed for years. These cases, I believe, are most commonly syphilitic, and in one case of this kind, on which I had occasion to operate, a dead portion of the os frontis was known to have been so for three years, and yet the chisel and the rongeur revealed no point at which separation had even commenced. This peculiarity of non-separation is also sometimes seen in necrosis of the lower jaw, where often the process of separating the dead from the living parts is unwillingly undertaken, and slowly and imperfectly performed. This feature is not always observed, exfoliation sometimes taking place promptly and completely. This I have seen in several traumatic cases, and in one case of syphilitic necrosis of the cranium, under the care of Dr. F. H. Hamilton, at Bellevue Hospital, one large sequestrum came away with ease as if already separated (Fig. 580). This was the more noticeable, because at most other points no evidence of separation could be discovered.

Fig. 580.

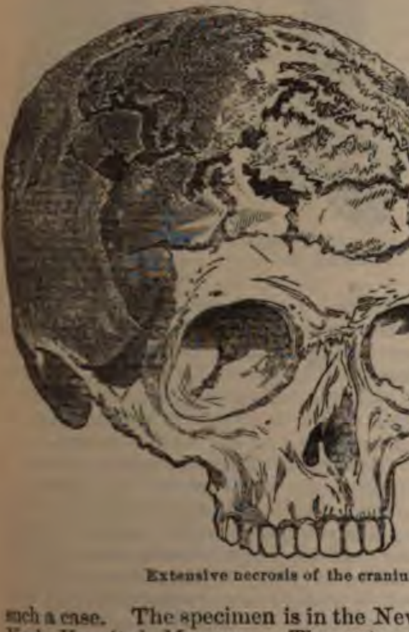


Large sequestrum from a case of syphilitic necrosis of the cranium.

Another feature of this disease, as it attacks the cranium, is a disposition to spread gradually and slowly over large districts of the skull. This progress is usually characterized by puffy swellings of the scalp, which slowly suppurate, and then ulcerate, destroying the entire thickness of the scalp. At the bottom of these ulcers, the bone is found to be bare and dead. This disease makes progress in two ways. 1st. By new puffy spots followed by ulceration disclosing dead bone, and 2d, by an extension of the necrosis itself, sometimes undermining the edges of the ulcer, and sometimes enlarging its area. This gradual extension of the necrotic action is almost peculiar to the flat bones of the skull. The death seems to be preceded by a thickening and roughening of the surface about to die, evidently due to a hyperæmic action in the bone-substance, but which makes no considerable advance as an active process, being so promptly followed by the death of the part involved, that the necrosis seems to advance by its own infective action rather than to be preceded by a vital bone change, which careful inspection, however, shows to have preceded actual death.

By this progress of steadily advancing necrosis, large districts of the skull are invaded, some times involving nearly the whole calvarium. Fig. 581 represents such a case. The specimen is in the New York Hospital Museum. The rate of progress of this form of necrosis is usually slow, several of the recorded cases having occupied years in their course. The depth of the destructive action varies very much at different points, in some involving only the outer table, and in some destroying the whole thickness of the bone. Some ulcerative or carious action is unquestionably set up in the course of the disease, for we find erosions and perforations of the bone at various points which can in no other way be accounted for. The dura mater opposite those points of bone entirely necrosed is thickened, sometimes granulating, and separated from the dead-bone surface by a layer of pus. This purulent collection commonly communicates with the external surface by means of the carious openings above referred to. The termination of several of the recorded cases has been by meningitis.

Fig. 581.



Extensive necrosis of the cranium.

The removal in these cases of the dead bone has usually given an imperfect result. Either it has been found impossible to remove all the dead portion, or after complete removal the disease has recommenced in the neighboring bone, and steadily advanced to a fatal termination. I do not believe that any remedies now known have any direct effect in arresting its progress.]

The same may be said of the necrosed portions of irregular bones, which consist almost entirely of cancellous tissue (such as those of the tarsus), in which necrosis is by no means rare. Whole bones, or large portions of entire bones, of the tarsus, and sometimes, but less often, of the carpus, are found quite separate from all their attachments, and merely retained as foreign bodies among the soft parts. In such cases there is sometimes a little difficulty in making the diagnosis; since the dead bone has not the hard ringing sensation usual in necrosis of compact tissue, and the large size of the necrosed piece sometimes prevents it from moving under the probe. The case, therefore, simulates one of caries.

> This difficulty was experienced in the case of a little child under the writer's care, in whom a sinus existed leading down upon the os calcis. The probe passed down to soft bone, not in the least movable, and crumbly to the touch. On the soft parts, however, being turned back, it was found that the posterior part of the calcaneum, involving at least half the bone, was dead and quite separated from the anterior part. This having been removed, the child made a rapid recovery. I have seen similar cases in childhood repeatedly, and more especially about the tarsus.

However, though the cancellous tissue is sometimes affected with necrosis, it should be remembered that this is exceptional, and that necrosis is an affection more peculiarly of the compact tissue, and especially of the densest bones. Thus the petrous bone is frequently necrosed, and has been known to exfoliate almost entire.[1]

[I have seen one of these petrosal sequestra which was removed by Dr. C. R. Agnew from a patient who had been long suffering with suppurative otitis media. His report of the case says: "It will be observed that the sequestrum includes the wreck of the labyrinth. The cochlea is seen laid open by caries, and two of the semicircular canals are seen in part. The vestibule is bereft of its furniture, and almost obliterated. After the operation the patient rapidly regained his health, and by the end of the year the external meatus had become closed by cicatrization."

Necrosis occurring after compound fracture is worthy of a moment's notice. The death of a portion of the ends of one or both fragments after compound fracture depends either upon the exposure of the injured bone to the air and the decomposing fluids of the wound, or to separation of a fragment from all its vital connections, so that it dies from want of nutrient supply. Practically perhaps this distinction is not of great importance, for the main fact we have to deal with is the presence of dead bone in the wound. This ordinarily does not declare itself in the early stages of the case, and it is only after the process of repair is far advanced, that we begin to find its completion hindered by the presence of a foreign body, which delays and will prevent final healing. This the probe easily discovers to be dead bone, and the chief clinical interest in the case lies in determining the proper time for its removal. Union is not by any means always prevented by these sequestra between the fragments, but, in many cases, it is weak and imperfect while the sequestrum remains, and becomes solid only when the offending body is removed. Fig. 582 shows a case in which a large original fragment which had become jammed between the ends of a broken femur almost entirely hindered union, the actions of repair being represented by some slender bridges of bone thrown out around the intruder. Fig. 583 shows secondary death of the extremities of both bones after compound fracture of the leg.

In the treatment of these cases boldness and thoroughness are the soundest surgery. A liberal incision should be made at the seat of fracture and enough of the callus cut away to expose the dead fragments and permit their complete removal. Of course care should be taken not to sacrifice any of the bond of union unnecessarily, but the removal must be complete or the wound will not heal. There is less reason to hesitate about these operations, because it is found that the new traumatism generally sets up new reparative activity, and therefore even in cases where the operation has been done without finding a sequestrum, a new impetus has been given to the process of repair, which was before sluggish and ineffectual, and under this new stimulus union has taken place and the wound healed.]

Necrosis of broken ends of tibia.

Treatment.—Hitherto we have been considering the usual method of separation; and as this is a long and tedious process, seldom completed under many months in the case of a large sequestrum, and often dating by years, it is not surprising that efforts should have been constantly made to anticipate the period of cure by cutting away the diseased bone. These, however, have hitherto resulted in disappointment. The process must be left to find its natural completion in the spontaneous separation of the dead bone from the living; and any attempt to effect this by operation, *i. e.*, to detach the necrosed portion, and to cut it away from the living parts, only extends the area of the disease, and endangers the preservation of the limb. Special considerations, applicable to some regions of the body, such as the skull, may indeed induce a surgeon to operate on necrosed bone before it is loose, for the relief of matter pent up below it: such operations, however, are not undertaken with a view of curing the diseased bone, but of restoring the function of organs secondarily affected. Such has been the result of surgical experience up to the present time. I have, however, pointed out above (p. 139), that a sequestrum of limited extent may be dissolved out by the action of sulphuric acid, or probably of potassa fusa, and thus the slow process of vital action necessary for its separation may be anticipated. In order to obtain success, however, in these proceedings, it is essential to know exactly the limits of the disease.

---

[1] Path. Soc. Trans., vol. vii., p. 335. A similar case occurred at St. George's Hospital, under Mr. Prescott Hewett's care; Museum, St. George's Hospital, series ii., 99.

But when the sequestrum has separated and lies loose and invaginated in new bone, surgical interference is most necessary. There is perhaps no part of surgery in which the improvements effected in comparatively modern times have done so much to preserve life and limb, and to obviate pain, as in the treatment of necrosis. The invaginated portion of bone can never get out by any natural process: the very completeness and efficacy of the efforts which nature makes to preserve the continuity of the bone, and to restore its strength, effectually imprison the dead portion. Small pieces or granules of dead bone constantly exfoliate from carious surfaces; but when the sequestrum is of any considerable size, the cloacæ are never so large as to admit of the escape of the sequestrum through them, although sometimes they are very nearly large enough. Thus, in the Museum of St. Bartholomew's Hospital, there is a curious specimen,[1] in which a small piece of loose bone, just too large to get out of any of the numerous cloacæ which have formed around it, is found rattling about in its cavity as if in a dice-box.

The requisite operation consists in cutting down on the dead bone, and exposing it sufficiently to remove it. If the necrosis be superficial, nothing is required beyond turning back the soft parts, which have no connection with the dead bone, elevating the latter, and pulling it out with a pair of forceps. But, for the removal of an invaginated sequestrum, it is necessary to open the sheath by enlarging one of the cloacæ with the trephine, or cutting forceps, until it is large enough to admit of the extraction of the piece. Sometimes, when the sequestrum involves a large portion of the shaft of the bone, it may be found impossible to get the piece away until a pair of cutting forceps or a trephine has been introduced through the enlarged aperture, and the dead bone divided. In the necrosis which so often attacks stumps after amputation, a ring-like piece may separate from the end of the divided bone. Its extraction is then a matter of considerable difficulty; but still, as there is a free opening on to the extremity of the dead bone, it may be accomplished with some little trouble. If a similar sequestrum should form on one of the long bones, involving a ferrule-like portion of its surface, its removal would be still more troublesome, requiring free incisions on both sides of the limb: but I am not aware that such cases have been noticed in practice.

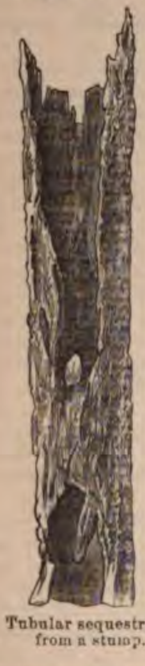
[Necrosis not unfrequently occurs in the sawn extremity of a bone after amputation. Commonly this necrosis is limited to a small ring of bone at the end, which may be supposed to have been injured by the violence of the saw, or which, by exposure to air and the decomposing fluids of the wound, has lost its vitality. These cases give rise to very little trouble, beyond keeping the wound from final healing, and are usually soon detached and easily removed.

There is another form of necrosis in stumps not so fully described, and, I think, often misunderstood. The clinical history of a case of this kind is about as follows: A healthy man undergoes amputation through the middle of the thigh for injury. He recovers well from the operation, the wound heals rapidly and well, and progress is satisfactory in every respect, until at the end of a month or six weeks, the stump, which should be soundly healed, shows still one or two fistulous orifices, from which a moderate amount of healthy pus is daily discharged, and which refuse to close. The stump is tender, and the patient suffers some pain in it, particularly when he attempts to leave his bed and go about. On feeling the stump it is large, full, firm to the touch, tender, and hot. On pressing deeply, the enlargement is found to be due to the increased size of the bone, which can now be perceived to be the chief seat of pain and tenderness. While this lasts the patient's general condition does not frankly improve, as might be hoped, and there is evidently something keeping him back from satisfactory convalescence. If now a probe be introduced into one of the openings bare and dead bone is immediately encountered. The pathological conditions accompanying this history are found to be a necrosis occupying the central part of the bone stump, extending from three to six, or even eight inches upwards, towards the trochanter. The dead part is found to be of a tubular shape, and corresponds with the inner lamella of the sawn bone, which inner layer of the bone has, for some cause or other, fallen into necrosis. The outer laminæ of the bone have become greatly thickened, and osteoporotic, and surround the dead lamella as any ordinary sequestrum is surrounded by its involucrum. This enlargement of the living bone, with the thickening of the periosteum, which is very great, explains the deep tumefaction, which was felt on handling the stump before dissection. The medulla is found within the tubular sequestrum, scarcely affected by the actions around it. The sequestrum is thus enclosed between two laminæ, which both have the bone-generating power, so that if the dead piece remain long enough *in situ*, it is engaged between two layers of bone, the outer being the involucral external lamina of the femur, the inner being the ossified medulla. Loose in its bed between these two lies the sequestrum, and if the stump be opened, and the projecting end be seized with the forceps, the foreign body can easily be drawn out.

---

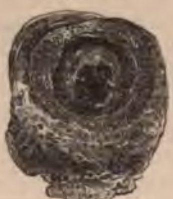
[1] Sub-series A, No. 94.

Fig. 584.



Tubular sequestrum from a stump.

Fig. 585.



End-view of the same bone.

It occasionally happens, however, that there are some openings in the sequestrum, through which osseous bridges shoot across from the outer to the inner involucral layer, and thus imprison a sequestrum, which is otherwise entirely loose, and could, but for this obstruction, be easily removed. Figs. 584 and 585 are representations of a sequestrum which was thus imprisoned, and which required an extensive operation to set it free. In the New York Hospital Museum we have quite a number of these tubular sequestra, varying in length from three to seven inches.

In explaining the occurrence of these peculiar sequestra writers have usually invoked the agency of osteo-myelitis in some form, which, it is believed, by depriving the inner lamina of nutrient fluid, and, perhaps, poisoning its tissue by foul and decomposing inflammatory secretions, has produced its death. That inflammation and suppuration of the medulla may and do sometimes produce more or less extensive necrosis cannot be denied; but such inflammation is a distinct and formidable disease, with serious constitutional as well as local symptoms. How then explain the occurrence of these sequestra when no such disease has affected the stump, and when, on the contrary, the whole progress of the case has been, perhaps, exceptionally favorable?

An explanation which covers all these cases is found in the relation of the nutrient artery to the medullary blood-supply. The medulla receives its chief supply from the main nutrient artery, which usually enters the bone by a single large foramen, and then divides into two sets of branches, one set for the medulla itself, and another which supplies the inner lamina of the bone, which looks toward the medullary cavity; the outer lamina of bone being nourished by vessels coming from the periosteum. This nutrient artery, in passing toward the foramen of entrance, has, in some bones, an upward course, so that a part of its career is outside of and below the nutrient foramen. If now, in making the incisions in amputating, this artery be cut below its point of entrance into the nutrient canal, then the inner lamina of the stump bone will be entirely deprived for the moment of its arterial supply. In soft tissues this temporary deficiency would immediately be obviated by the enlargement of the anastomosing vessels, which would promptly bring a sufficient supply to maintain life, and finally restore the equilibrium. In the bone, however, with its whole vascular system enclosed in rigid and unyielding bony canals, this secondary supply may come too slowly to save the lamina, deprived entirely of its arterial supply, from immediate death. The medulla itself will not perish, for its anastomotic supply is easy and abundant, and the external lamina is, of course, not affected by the calamity which has befallen the inner one. From all this comes the fact, which careful post-mortem study demonstrates, that the dead lamella is enclosed between two living walls, the outermost being the original bone, and the innermost being the surface of the medulla, which, after a time, becomes the seat of osseous deposit, forming the inner tube of enclosure, thus causing the section of such a bone to give three concentric circles, the outer one being the original outer lamella, the inner circle being the ossified surface of the medulla, and between them a ring composed of a section of the tubular sequestrum of the inner lamella, which has perished as above described.

This anatomical arrangement of the three laminæ, two living and one dead, is well shown in fig. 585, which represents the sawed end of a femur stump, some months after the removal of one of these tubular sequestra. The stump had re-ulcerated in consequence of a fall, and it became necessary to saw off an inch and a half of the end of the bone. Of course the dark middle space indicates the cavity from which the sequestrum had been removed, and not the sequestrum itself.

The explanation of this necrosis, given above, becomes more probable when we remember that, in a very large proportion of femora, the nutrient artery runs upwards, and enters the bone at a point about the middle, or just above the middle of its shaft. In the humerus the nutrient artery enters the bone above its middle, and its course is from above downwards, saving it from the possibility of being cut off before it enters the canal, as must so often happen in the femur. I have never seen one of these sequestra in the humerus, and I know of no case in the tibia, where also the course of the nutrient artery is from above downwards. Such an accident might be possible in the radius or the ulna, where the direction of the artery is from below upwards.]

A preparation in the Museum of St. George's Hospital (series ii., 75) shows a strip of necrosed bone winding spirally, for a considerable distance, round the shaft of the humerus.

It has sometimes been made a question whether the sequestra of necrosed bone can be removed by a gradual process of disorganization and molecular decay. If this question be proposed as an essay in scientific pathology, there is no doubt of its great interest; but viewed as a practical consideration in surgery, hardly any value attaches to it. Experiments on animals certainly appear to show the possibility of the removal of small pieces of excised bone re-implanted in the excision-wound;[1] and it is possible that, in the human subject, sequestra of bone may be to some extent eaten away by a process of absorption like that which sometimes removes the ivory pegs driven into bones for the cure of ununited fracture (see Vol. I., p. 509);[2] but even allowing all upon this head which any one could reasonably deduce from such facts as these, we should still be justified in saying that the process is so slow, so uncertain, and so partial, that no account ought to be taken of it in surgery.[3]

It is therefore necessary, in every case in which a sequestrum forms, that a surgical operation should be undertaken for its removal. The word *sequestrum* is here used in its strict sense, to express a portion of dead bone contained in a case of new bone. An *exfoliating* portion of bone may separate and be thrown off by the natural processes, though it is usually necessary to facilitate its removal when loose by incisions.

A question is sometimes raised, whether it is prudent to operate as soon as the operation is possible, *i. e.*, as soon as the bone is loose, or whether a certain time should not rather be given, in order that the newly formed bone may become consolidated, and the limb sufficiently strong to perform its functions. The question, however, is rather fanciful than practical. No harm appears ever to result from taking away a loose piece of bone, but much mischief often follows on its being allowed to remain. If, in rare cases, the bone is left too weak to bear the weight of the body or the motions of the limb, it is probable that this is a consequence, either of such extensive destruction of periosteum as finally to preclude reproduction, or of some constitutional fault, or other predisposing cause. The inflammation excited by the presence of the sequestrum in the neighboring bone has probably not passed the stage of softening; while, from the same low rate of the morbid processes, the bony deposit furnished by the periosteum has been small in quantity and low in organization. In such a case as this it would appear that the best chance for restoring to the bone its proper density would be afforded by the operation which would relieve it of the cause of the inflammation whereby its cohesive power is being destroyed. It would, therefore, be far more rational to remove the dead bone, and put the limb at rest, than to leave the source of irritation, and expect a cessation of the effect from perpetuation of the cause.

---

[1] Heine, in Gräfe und Walther's Journal, Bd. xxiv., p. 527, quoted by Wagner, op. infra cit., 146.

[2] A case showing this absorption very clearly has been put on record by Prof. Cleland, in the Brit. Med. Journ., for Feb. 22, 1868.

[3] It may reasonably be doubted, also, whether the absorption said to have occurred in some of the experiments above referred to did really take place, or whether the whole thing was not a mistake on the part of the experimenters. Gulliver's experiments (Med.-Chir. Trans., vol. xxi.) show that portions of loose bone, thrust into the tissues of living animals, may remain an indefinite time without experiencing any absorption, as proved by careful weighing at the beginning and end of the experiment. Again, cases such as that quoted on p. 143 prove that a portion of bone, of no extraordinary size, may remain necrosed during a great part of a lifetime, and suffer no perceptible diminution in size. This is the case even when its mechanical connection with the rest of the body is not entirely destroyed. But surely when loose and separated from the living tissues it must be still less under the influence of the vital actions. In a paper by Mr. Savory, in the Med.-Chir. Trans., vol. xlvii., several experiments are described, showing that the absorption of dead bone driven into the living bones of animals, is proportional to the pressure to which it is subjected, a condition which hardly exists in the cases of necrosis that occur in practice.

It is not always easy to determine the question, whether the bone is loose or not, since the growth of the periosteal sheath, or even the shape of the loose portion, and the arrangement of the parts around it, may prevent it from moving under the probe. Of this fact an instance has been given above (p. 149), and the reader may consult a clinical lecture by Mr. H. Smith, Medical Times and Gazette, March 22, 1862. In cases, therefore, where the disease has lasted so long that the separation may be reasonably expected to be complete, it is right to endeavor to remove the bone, even although the probe has not given decisive evidence that the operation can be carried out.

It is necessary here to say something respecting the agents, and the manner, of regeneration of bone after loss of substance from necrosis. In doing this, however, it would be impossible in an essay of this sort, to go into the question with any approach to completeness; but it is hoped that enough will be found in the following paragraphs to illustrate the points necessary for practice. The student who wishes to learn more about the matter is referred to the works of Troja, Weidmann, Flourens, Syme, and Wagner.

The most important agent in reproducing bone lost by necrosis is, without doubt, the periosteum; and this membrane is sufficient of itself to replace all the ordinary exfoliations and partial necroses which follow injuries, etc. The osteogenic properties of the periosteum, when in contact with the bone, have long been known, in fact must have been apparent when the function of the membrane was first studied; and that periosteum, when separated from the surface of the bone, will still generate new bone, is no very novel discovery, since John Bell seems to have been perfectly acquainted with the fact, and describes the formation of a bony cyst by secretion from the detached periosteum, around a collection of blood which had dissected off that membrane from the bone;[1] and the experiments of Syme and Stanley are well known. Lately the osteogenic powers of periosteum have been placed in a very striking light by the experiments of M. Ollier, of Lyons.[2] He has shown that, in rabbits, portions of periosteum may be entirely detached from the bone, and pushed into the cellular tissue of the limb, or even grafted into remote parts of the body, or into the body of another rabbit, and that bone would be generated from the fragment of periosteum in this novel position. He has even succeeded in producing bone by such grafting of portions of periosteum kept for more than an hour out of the body.

It is far from certain, nay, it is most improbable, that any such results could be produced in man, since the conditions of all reproductions, and especially of reproduction of bone, are known to differ so much in man and animals; but, even if the vitality and osteogenic power of the periosteum be less in the human subject than in the lower animals, still it seems reasonable to infer, from observed phenomena, that that power is of the same nature; so that these striking experiments may serve to fix more firmly on the attention of surgeons the importance of preserving the periosteum in cases where the reproduction of lost bones is in question. In all cases, then, where loss of substance in bone has taken place, or where the bone seems deprived of life, it is of the greatest importance that the periosteum should be preserved, a point which will be noticed again in the essay on EXCISION, in speaking of sub-periosteal resection.

---

[1] The Principles of Surgery, by John Bell; a new edition, by Charles Bell, 1826, vol. iv., p. 406. The pathology of the case, as related by the author, is sufficiently obscure; but the case may be used to show that Bell knew that bone could be formed from the detached periosteum.

[2] British Medical Journal, 1860, pp. 398, 438; Traité de la Régénération des Os, Paris, 1867. I may mention that some of M. Ollier's experiments have been repeated and verified by numerous experimenters, amongst others by myself.

It has frequently been made a question, on what this power of reproduction depends, whether on the action of the fibrous membrane itself, or on the detachment, together with its lower strata, of small particles from the surface of the bone, which serve as nuclei, around which new bone grows. It is not easy to prove that such nuclei are not detached in every case; but there is no evidence that such is the fact. Bone has often been known to be produced from portions of periosteum which had been previously carefully examined, and no such particles found; while in other cases it has appeared probable that the periosteum had carried fragments of bone away with it. M. Ollier considers that a "subperiosteal blastema" exists naturally between the periosteum and bone, and that this is the source of the deposit.

The periosteum, however, although the most important, is not the sole agent in the reproduction of bone; so that it may be confidently expected that bone will be reproduced in healthy subjects, even though the periosteum be extensively destroyed; but the reproduction will not be so complete as if that membrane had been left. Such a process of reproduction may often be watched in cases where the soft parts have sloughed after scalp-wounds, and have left the cranium exposed.[1] The accident will often be followed by exfoliation from the surface of the bone; granulations then shoot up from the bony surface so exposed, and these are joined by others which advance from the soft parts in the neighborhood: a fibrous cicatrix is formed which can be felt gradually hardening and ossifying. If an opportunity occurs for examining it after the lapse of some considerable time (say half a year), it will be found that the fibrous tissue of the cicatrix is ossifying at its deepest part, and scattered granules of bone will probably be met with at various parts of the cicatrix.

This process may go on even when the bone and periosteum have been removed by operation, as in the wounds of resection,[2] but is much more active when previous inflammation has been excited in the medullary tissue and surrounding soft parts, during the action necessary in order to eject a piece of necrosed bone. In fact, speaking generally, the process of reproduction after necrosis is beyond comparison more active than after injury or operation. Thus, when necrosis has preceded the operation, whole bones of the forearm have been removed, and yet a useful limb has been preserved.

In a case which I had an opportunity of seeing, in which Mr. Savory removed the entire shaft of the radius on account of necrosis, leaving the articular ends,[1] the bone had grown from each of these ends to so great an extent that in eight months after the operation there remained an interval of only an inch and a half, and this appeared to be gradually, though slowly, contracting. This and several similar cases will be found quoted in Wagner's treatise above referred to, and may serve as an encouragement for boldness in our attempts to save limbs after extensive necrosis.

The exfoliation of diseased portions of bone, such, for example, as takes place so frequently in the course of extensive strumous disease, when a portion of the ulcerated surface is cut off from the rest, and therefore perishes, is not generally accompanied by any of that reparative effort which forms part of the process in a more healthy condition. The mere presence of necrosis in such affections is of comparatively little importance; possibly the removal of the dead part may be advisable (but only if it can be done without much violence), but the operation cannot be expected to cure the disease, since the necrosis is not its cause, but its effect. Nevertheless considerable improvement may, in appropriate cases, be expected to follow on the removal of the dead portion, which must always act as an irritant; and the exposure of the carious surface is also very frequently the starting-point of a more healthy action. Hence when bone is felt exposed and dead, it is usually advisable to endeavor to remove it, even although the surface around it is known to be carious.

The above description applies to necrosis in its more usual form. But besides this common chronic form of the disease, an affection which deserves the name of *acute necrosis* is sometimes, though not very often, met with. The destruction of all the soft parts surrounding a small bone, as a phalanx in acute neglected whitlow, will of course lead to the exfoliation of the whole of it, and to this affection the name of acute necrosis is sometimes given. There is nothing, however, in the pathology or treatment of such a disease to call special attention to the bone. The rapid and tensive inflammation threatens other parts of equal importance—the joint, the tendons, nay, in some cases even the skin—with destruction; and the free evacuation of the products of the inflammation is the only measure from which any good can ration-ally be expected. But there is a less-known class of cases in which larger bones are involved in rapid destruction, without known cause, or from causes apparently quite inadequate; and such cases involve not merely local mischief, but very grave danger to life. Many such cases of rapid necrosis are the result of that diffuse inflammation of the periosteum which has been described above; but in others which I have had an opportunity of seeing, I have failed to detect such a cause for the death of the bone, or indeed any cause to which so extensive and so universal an action could reasonably be ascribed.

---

[1] See Wagner, On Repair after Resection of Bones (New Syd. Soc.), Appendix, p. 241, for a case in which this form of reproduction is well described.

[2] See Wagner, op. cit., p. 156.

[1] See Wagner, op. cit., p. 243.

Such a case was the following: A stableman was admitted into St. George's Hospital on account of disease in one foot. The history was obscure, but it seemed certain that little more than three weeks before his death the foot was comparatively well, as it was to an injury supposed to have been received twenty-two days before his admission, in running violently down the stable-yard, that the disease was attributed. There was œdema, swelling, and pain over the dorsum of the foot; and this condition was attributed to diffuse cellular inflammation, and treated by superficial incisions, which did not penetrate the periosteum. The man died, with symptoms of pyæmia, but no secondary abscess, twenty days after his admission. On examining the foot, all the tarsal bones were found loose, and grating on each other like stones in a bag; the cartilages between them had almost entirely disappeared. On section, the bones were of a dark-gray hue, and some slight trace of pus was seen here and there in the interior, but no such distinct indication of inflammation of the lining membrane of the cancelli as to deserve the name of osteo-myelitis; nor was the periosteum thickened, vascular, or separated from the surface of the bone by either lymph or pus in any appreciable quantity. The surfaces of the bones exposed by the removal of the articular cartilages were ulcerated, but not deeply. The bones were of their natural consistence.

Is such an affection as this amenable to any treatment? This seems doubtful, if it be conceded that cases of acute necrosis really exist in which the affection is different from diffuse periostitis. In the latter affection timely incisions may succeed, as has been already said, in checking the effusion and restoring the nutrition of the bone; but if the whole bony tissue be involved at once, what agency can be reasonably expected to restore it to health? It is clear that the main question in such a case is, whether the patient's powers will endure the strain of the disease, so that the bone may be cast off, and he may have the chance of its reproduction, or whether amputation will give him a better prospect of life. But the prognosis of an amputation undertaken under such circumstances would be in the highest degree unfavorable, since the condition of system in which such grave results can follow from such trivial injuries leaves little prospect of bearing up against so serious an injury as the removal of a limb; and the tendency to pyæmia is so strong that it is impossible to say that that condition of the system may not be actually present, though latent, when the operation is done. It will, therefore, in most cases, be judged better to support the patient's strength by a liberal allowance of tonics and opiates until the graver dangers have passed away; and then, if the usefulness of the limb is hopelessly destroyed, to remove it when the patient has rallied from the typhoid condition in which the disease commences. Incisions may not have the power of averting the death of the bone, but they ought to be made to an extent sufficient to liberate all tension, and that for two principal reasons—partly in order to avoid sloughing of the periosteum, and consequent destruction of the nidus in which the new bone is to be formed, partly to provide a ready way for the pus, which must form, to escape, and for the examination of the bone and its eventual extraction.

Acute necrosis, whether resulting from diffuse periostitis or not, may be treated by the extirpation of the whole bone so affected, a very free incision being made through the periosteum, which will be found completely separated from the bone, and the bone being, if necessary, divided by a chain-saw passed underneath it. In cases of necrosis of the entire diaphysis of a long bone, a slight twist with the lion-forceps will detach the dead portions from the epiphyseal lines above and below. In this way I removed successfully the whole shaft of the tibia (seven and a half inches long), at the age of ten, one month after the commencement of acute periostitis, with very successful results.[1] I think, when we have clear reasons for believing that the necrosed bone will be found loose, its early removal is most desirable, and liberates the patient from great dangers, both in the present, from the acute surgical fever kept up by the irritation of the diseased bone, and in the future, from the risks incident on the numerous and severe surgical operations which will probably be necessary for the removal of so extensive a sequestrum. I do not recommend the operation when a portion only of the diaphysis has perished, and has not yet separated. The old idea that it is necessary to wait in these cases for the formation of a periosteal sheath of bone, is sufficiently refuted by my cases and that of Mr. J. Bell, which show that even in so large a bone as the femur a great portion (and I do not see why not the whole, if such a case should occur) of the entire circumference of the shaft may be removed, and the limb be left perfectly flail-like after the operation, and yet entire consolidation and perfect usefulness of the limb may finally result.

---

[1] Lancet, 1866, vol. i., p. 340. See also Surgical Treatment of Children's Diseases, 2d edit., p. 391 et seq.; where other instances under my own care are related; also a case by Mr. Joseph Bell, Brit. Med. Journal, May 2, 1868, very similar to a case of mine in the femur, but more extensive.

CONSTITUTIONAL AFFECTIONS.

Scrofula in bone.—There are two forms in which scrofulous affections of bone are met with: viz., either a deposit of tubercle, or a low inflammation of the osseous substance; and there is good reason for considering the former as a consequence, or effect, of the latter. Let us, then, first consider the peculiar or distinctive characters of scrofulous inflammation of bone.

A scrofulous bone, when examined in the early stage of the disease, is soft, light, and oily; sometimes more highly charged with blood than natural, and occasionally (though only rarely) presenting a deposit of tubercle in its interior. Bones in this condition are constantly met with after the removal of scrofulous joints; the substance of the bone is easily cut with a knife, and the cancelli are large, and charged with a red jelly-like mass of débris. The inflammation readily passes into ulceration, or caries, and the bone then exhibits on its surface a number of minute pits, or depressions, from each of which the ulceration extends, so as to communicate with those around, until an extensive worm-eaten surface is exposed,[1] soft and rotten on its exterior, bleeding readily, and giving exit to a foul-smelling ichorous pus, in which pieces of decomposed bone can be felt, as gritty particles under the fingers. The periosteum becomes detached and thickened, and is gradually converted into a gelatinous mass of granulations.

The minute changes in the ultimate tissue have been ably described by Dr. Black, in a series of researches to which my own observations lead me to assent. The cancelli are dilated, and they, as well as the lacunæ and canaliculi, are filled with exudation. Occasionally, minute projections of bone from the walls of the cancelli indicate an attempt at the reproduction of bone, and that healing by sclerosis which has been already described as one of the usual events of healthy inflammation. The leading features, then, of the pathological anatomy of strumous inflammation are the same as those of osteitis in general; and the only distinctive anatomical peculiarity consists in the nature of the exudation, which chokes up the canals of the bone. Dr. Black has given several analyses, tending to establish these four conclusions: that tuberculosis gives rise (1) to a considerable increase of fat in the diseased bone; (2) to a large diminution of the salts of lime; (3) to a diminution of the organic matrix; (4) to an increase in the soluble salts. For the details of the analysis, the reader must be referred to the original treatise.[1] They serve to illustrate the fact, that strumous is distinguished from common inflammation by the softness, lightness, and oiliness of the affected bone; to which may be added, the greater extent of diffusion of the morbid changes.

The superficial caries, during the mere presence of which the bone, if the affection be not very extensive, is possibly still in a curable state, spreads gradually inwards, and then the condition of the bone passes beyond the possibility of repair. Large abscesses form, and the whole cancellous extremity, or the whole bone if it be one of the cuboid bones of the tarsus or carpus, is converted into a cavity bounded by a thin shell of osseous matter, and containing bony substance, either in mere débris, or so soft that it will crumble away in maceration. These abscesses are seldom accompanied by that thickening of their walls from periosteal deposit which takes place in simple osteitis; still, at some distance from the seat of profuse suppuration, fresh deposit is sometimes found thickening the bone, or producing anchylosis in joints which enjoy little motion. Necrosed portions of larger or smaller size are often found, but no "sequestra" in the proper sense of that term, as signifying necrosed portions invaginated by new bone.

Such are the anatomical characters of scrofulous inflammation of bone. The other common development of that diathesis in the osseous system consists in the deposit of tubercle, either circumscribed or diffused. Circumscribed tubercle[2] (much the rarer form) seems most common in the skull, deposited on the outside of the bone beneath the periosteum (the strumous node); and next to this its favorite locality is in the cancelli of the joint-end of some bone, generally the tibia. No inconvenience seems to be produced by such tubercle till it softens; and then, if situated in the articular end of a bone, it usually makes a passage into the neighboring joint and destroys it; if on the skull, the softening of such a tubercle forms a cachectic abscess difficult to heal, bordered by indurated cellular tissue, with cold, bluish edges, and leading to exposed and roughened bone, which, however, has not the peculiar feeling of necrosis, and is not at first dead, although it is liable to become so. The deposit of diffused tubercle is more common in the shafts of the long bones. It fills up the cancelli, appearing as a nodulated, or granular, yellowish mass of soft consistence, and extends frequently along the whole length of the shaft. My own impression is, that this diffused tubercle less frequently and less rapidly softens than the circumscribed; but exact information on this point is wanting. It should be remembered that when the shaft is attacked by this or any other form of disease, the extremities usually escape, and *vice versâ* —a matter of great importance in the treatment of diseases of the joints.

---

[1] For the appearance of scrofulous ulceration in the macerated bone as contrasted with simple ulceration, see figs. 575, 576, p. 135.

[1] On the Pathology of Tuberculous Bone, p. 32. Edinb., 1859.

[2] Tubercle in bone is, in any view of the case, rare. Rokitansky's statistics, referred to in vol. i., p. 163, give a low place to the bony system as a seat of tubercle; though they place the bones and periosteum consid-

It has occurred to me, though hitherto only on two occasions, to meet with a particular form of ulceration, which was in one case certainly,[1] and in the other probably, connected with scrofula. Numerous pits were found on the articular surface, varying in depth, but confined to the epiphysis, with sharp edges, and curdy purulent contents. Their openings into the cavity of the joint were cleanly punched out of the cartilage, and all the cartilage around was quite healthy. A few small granules of bone were met with among the contents of the cavities. In one of the cases, when the bones were examined, there were found several spots of vascular and softened tissue beneath the surface of the bones, evidently the commencement of similar pits. There was no trace of tubercle. The thigh was amputated, and the patient recovered for a time, but soon died of phthisis. In the other case, the patient, a boy under the care of Mr. Thomas Smith, recovered after excision of the knee, and remained long afterwards in good health.[1]

I believe this pitting or spotted ulceration of the articular ends of bones to be one of the forms of scrofulous disease, and to be indistinguishable from its other forms before dissection. It presents a very favorable condition for resection, from the strict limitation of the disease to a very slight depth below the surface.

Symptoms.—Of the symptoms of scrofula in bone little need be said here. The general symptoms of the diathesis, added to an indolent swelling of some bone, lead to a diagnosis not to be mistaken. The swelling is composed partly of the engorged soft tissues, and partly occasioned by real enlargement of the bone. The color is usually white and pasty,[2] and the swelling indolent; but sometimes, when the inflammation is higher than common, and suppuration imminent, redness and pain may be present. When suppuration has been effected, the pain generally subsides, and the functions of the part are more or less completely regained, even when the bone is destroyed to a considerable extent.

Treatment.—The treatment of scrofula in bone offers little that is peculiar. For local treatment, perhaps the most important indication is to keep the part at rest by splints and bandages during the prevalence of inflammation. Local depletion should be cautiously used while there is pain, tenderness, and superficial redness, or the part may be enveloped in a large warm poultice or fomentation. When inflammation is not apparent in the soft parts, but there are signs of its presence in the bone, it will be necessary to use counter-irritation by caustics or blis-

---

erably above the testicle and epididymis, which is hardly in consonance, I believe, with the experience of most surgeons. But the nature of the deposit generally spoken of as tubercular is the subject of much difference of opinion among different pathologists. Dr. Wilson Fox says: "These limitations of tubercle have proceeded so far, that, if the exclusion of the different forms from the category of tubercle, proposed by various pathologists, were simultaneously carried out, tubercle would—not, unfortunately, cease to exist—but would certainly have no longer any place in our nosologies; for nearly every pathological product hitherto ranked under this title, from the gray granulation to the yellow granulation and the cheesy infiltration, is by some authority or other excluded from the category of tubercle."—Artificial Production of Tubercle, p. 22. My opinion is, that many of the deposits which are usually regarded as tubercles in bone, are masses of inspissated pus mingled with other inflammatory products; and that, rare as tubercle in bone is generally said to be, it is in reality still rarer.

[1] A notice of this case will be found in Path. Soc. Trans., vol. x., p. 217.

[1] This is figured in the work above referred to, On the Surgical Treatment of Children's Diseases, p. 488.

[2] The "white swelling" of old authors was named from strumous disease of the joints, though many other affections came to be included under the term.

ters; or in less severe and more chronic cases by means of the tincture of iodine, or other stimulating application. When irritation has subsided, pressure by means of strapping will be found very serviceable, both in ensuring rest and in promoting absorption, and the local action of mercury (Scott's bandage) may be combined with this. By these simple measures, with judicious constitutional treatment, most of the cases of strumous inflammation, which are seen before the occurrence of suppuration, will be brought to a favorable issue.

When the suppuration is once established, it is better to procure exit for it by small incisions, and to use every precaution to prevent the denudation of fresh portions of bone. The question, however, of the early or late opening of abscesses connected with strumous bone is one on which a good deal of difference of opinion very naturally exists, and which is best determined in each individual case. If such abscesses are allowed to go on increasing, the soft parts may be extensively undermined, the disease may extend to fresh bones, and an opening may form in a disadvantageous situation. If opened early, the cavity may be attacked with inflammation, which, if the abscess be large, may even prove fatal. If, however, the abscess be near an important organ, as a joint or serous cavity, then undoubtedly no time should be lost in evacuating it. Large openings should be avoided; but the introduction of a piece of lint, or a drainage-tube, will keep the discharge flowing; or the abscess may be emptied by means of a trocar from time to time, and the access of air thus effectually precluded. When the bone is exposed through the opening of an abscess, its condition should be thoroughly investigated, once for all, with the probe, in order to judge of the necessity for operative interference; but nothing is more mischievous than repeated meddling with diseased bone. The general indications for operations upon bones affected with strumous caries, and the form of operation indicated, will be the same as in caries depending upon other causes; but the prognosis will be less favorable than when the constitution is unaffected, and therefore operations should be undertaken with more caution. Operations on these cases will usually succeed or fail according as scrofula has attacked the viscera or no, and according to the extent of its diffusion through the system; but even after a successful operation the patient is by no means secure against a relapse in some other part.

For the general treatment the reader must be referred to the essay on SCROFULA.

Syphilitic affections of bone.—The chief phenomena of the syphilitic affections of bone have been already spoken of summarily under the head of Tertiary Syphilis (Vol. I., p. 224); it will therefore only be necessary here to go a little more into detail as to the anatomy of bone affected by syphilis, and the means by which the disease is to be diagnosed. As the general treatment of syphilis has been laid down in Mr. Lee's essay, only the local treatment of its manifestations in the osseous system will be dwelt on here.

Syphilitic affections are those in which the existence of a chronic limited inflammation of the periosteum alone is most clearly proved, if, indeed, such inflammation be not peculiar to syphilis. Strumous nodes (as we have just remarked, p. 158) are formed by scrofulous matter confined between the carious bone and its periosteum, and are due to an affection of the bone; but the true node, that which follows syphilis, is caused by the effusion of lymph between the bone and periosteum, and is due to inflammation of a limited portion of the deeper layers ("subperiosteal blastema") of the latter. Hence it is of a different signification from that of a strumous abscess; for while the latter is merely a consequence of diseased bone, and necessarily involves corresponding loss of substance and the slow processes by which alone an ulcer (and more especially a strumous ulcer) in bone can be healed, the syphilitic node is itself the starting-point of the disease in the bone, and if early and properly treated, the whole organ can be restored in a short time to a state of health. But although in a node the inflammation is usually limited to the periosteum, it is not always so. Numerous preparations show thickening of the substance of the bone beneath nodes,[1] proving the implication of the deeper structures, and therefore a state of disease which, though still curable, may be expected to be more obstinate than mere periosteal effusion; and if the skull be examined in the situation of a node, some roughening of its outer table may generally, perhaps always, be discovered. The progress of nodes, when they are not absorbed under appropriate treatment, is in one of two directions: either the subperiosteal effusion ossifies, or it softens and gives rise to caries, accompanied usually by suppuration. The former event is commoner on the tibia, the latter on the skull. The indisposition of the pericranium to form new bone is a very well known fact in pathology, nor am I aware that the formation of new bone in syphilitic nodes of the skull has ever been proved, though new bone may be sometimes found deposited on the outer table of the skull in the neighborhood of large ulcers;[1] in nodes of other flat bones also, ossification, if it occurs, is rare. Many nodes appear so hard as to be pronounced osseous; but the feeling is often deceptive, since the tense and thickened periosteum raised by semi-solid effusion gives a sensation hardly to be distinguished from that of a bony swelling. Therefore, in a hard node which is of no long standing, treatment for its removal may be confidently recommended, and all the more if the swelling be situated on a flat bone. On the tibiæ nodes are prone to ossify, and then the deeper ossified part remains as a permanent irregularity on the surface of the bone; but the unossified portion may often be dispersed by appropriate measures. When a node softens, and the question occurs whether pus has formed, the case ought to be carefully examined, in order if possible to determine the point. The principal indication of the presence of pus is the shining, tense, and thinned condition of the skin. It is important to obviate more destruction of the skin than is inevitable on the bursting of the abscess, since such sores are very difficult to heal, and in some cases appear incurable. The best way is to make a very small puncture, and close it after drawing off the pus. Frequently, under the proper treatment, the soft parts will adhere again to the bone with very slight or no exfoliation.[2] It is especially in these cases of abscess communicating with the surface of a bone that I have found the treatment by carbolic acid, recommended by Professor Lister, most successful. In several cases under my own care where I have had either positive proof or the strongest reasons for concluding that the abscess was connected with diseased bone, I have found the abscess heal readily, and without exfoliation. Many others have also been put on record by Professor Lister and other surgeons. Very commonly, however, the formation of periosteal abscess after a node is followed by the exfoliation of most of the adjacent bone. Syphilitic nodes are usually preceded, and always accompanied, by more or less of dull aching pain in the bone, especially liable to exacerbations at night; or this "syphilitic rheumatism," as it is sometimes called (the *douleurs ostéocopes* of French authors), may be the only symptom referred to the osseous system during the progress of the secondary affection. Mr. Parker[1] is inclined to refer the pain to a syphilitic inflammation of the medullary membrane.

---

[1] St. Thomas's Hospital Museum, series c, No. 54.

When the syphilitic cachexia is further advanced, the whole bone or a great part of it may be diseased through its entire thickness, leading to chronic osteitis, and terminating in sclerosis, or what is sometimes called "hypertrophy" of the whole thickness of the bone. I am not aware of any distinction which could be drawn between such instances of chronic inflammation and those arising from non-specific causes, except that which is founded on the presence of concomitant and preceding syphilitic symptoms in other organs.

Still more grave and more obstinate developments of tertiary syphilis in the bones are those carious and necrotic affections (ulcerative or gangrenous) which so often attack the skull, the bones of the face, and the superficial long bones, in persons much reduced by excesses, or by the injudicious administration of mercury. In former times, under the horrible system which prevailed in the "foul wards" of the great hospitals, where every person laboring under any disease supposed to be caused by promiscuous intercourse was compelled to take mercury to salivation, the ravages of syphilis on the bones were dreadful; and it is to this system that we owe many of the preparations of syphilitic caries and necrosis preserved in our museums. But there seems no reasonable doubt that such affections do also occur in persons who have never taken mercury,[2] especially when the disease has been allowed to go on unchecked, and the constitution is at the same time enfeebled by alternations of debauchery and hardship, as is the case sometimes with sailors, and more frequently with prostitutes.

[Fig. 586, taken from a specimen in the New York Hospital cabinet, illustrates the fearful destruction which syphilis may sometimes inflict on the bones. "The disease was found to have destroyed almost the whole of the petrous portion of the temporal bone. The dura mater had either been absorbed or decomposed, and an immense collection of pus extended along the whole base of the brain. After maceration, the remainder of the temporal and a large part of the left half of the occipital bone, extending into the foramen magnum, the left portion of the body of the sphenoid and a part of the

[1] Even here it is in most cases doubtful whether the deposit has been formed outside the skull, or whether the thickening is not produced by deposit within the diploë expanding the outer table; for deposit in the diploë is exceedingly common. See below on the "tuberculated" form of syphilitic ulceration in bone.

[2] See Parker, Modern Treatment of Syphilitic Diseases, 4th ed., 1860, p. 291.

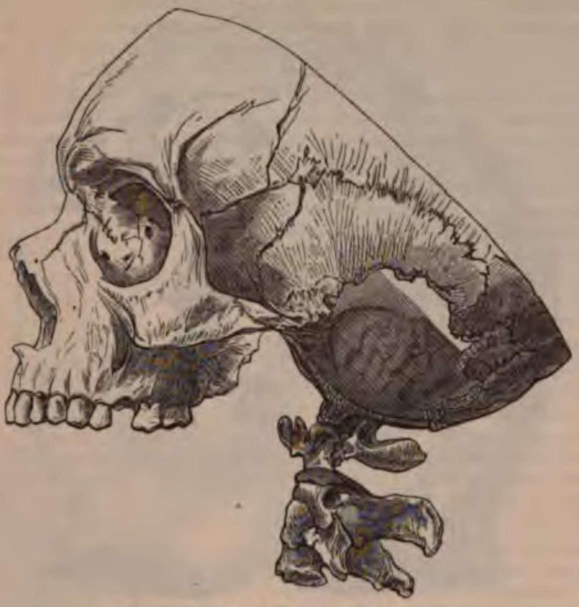
[Fig. 586.



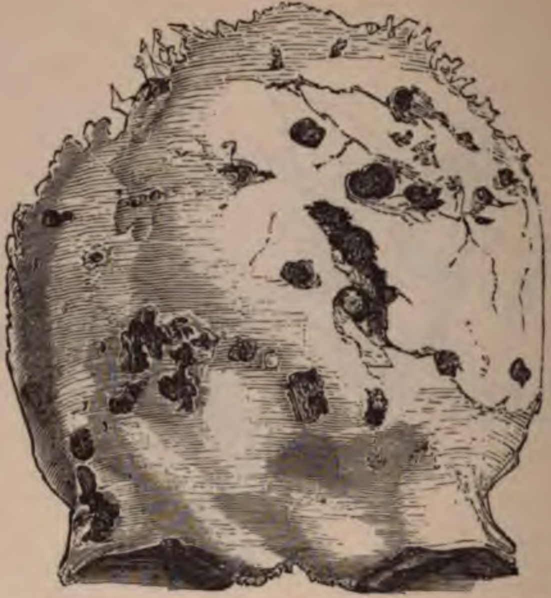
Destruction of bone by syphilitic disease.

arch of the atlas, were found to have crumbled to pieces, thus leaving a hole admitting the closed fist."]

The diagnosis of syphilitic affections is usually easy from the history of infection and the presence of other symptoms; but it may in some cases be obscured by the patient's unwillingness or inability to reveal the history of the original disease. Thus the pains in the bones may be referred to rheumatism; but here the diagnosis can in most cases be easily established by observing that rheumatic pains in the bones are generally accompanied by affections of the thick fibrous structures (muscles or fasciæ) and of the joints; or, if the rheumatic affection be more acute, the urine and sweat will probably furnish indications of the nature of the disease. When nodes have made their appearance, the diagnosis is usually easy, the only question lying between syphilis and struma, since rheumatic periostitis is, as we shall see, more diffused. In the absence of history, the concomitant symptoms will guide us while the skin is unbroken; and after pus has made its way to the surface, some assistance may be derived from the nature of the secretion. Syphilitic caries and necrosis (as has been observed in the essay on SYPHILIS) are not primary affections of the bones, but are the result and termination of nodes, or of inflammation of the bones, or of ulcerative affections of the soft parts around the bone, as in the palate, and therefore have been preceded by a long course of symptoms, during which the diagnosis is usually established. If not, it rarely presents any difficulty, since the traces or the presence of other symptoms of constitutional syphilis can hardly fail to be recognized.

An interesting comparison has been made between the forms of syphilitic ulceration in bone and those of syphilitic eruption on the skin. Specimens of rounded ulcers may sometimes be met with, especially on the skullcap, which bear a strong resemblance to the rupial ulcers so frequent in an advanced stage of constitutional syphilis. A small round spot of ulceration is seen, where the surface of the bone is worm-eaten from the presence of numerous minute depressions, and in some cases the bone around this worm-eaten central portion is marked by arborescent grooves, the traces of increased vascularity. Later on, a circular trench is marked around the worm-eaten spot; and as this widens and deepens, it undermines and finally chisels out the piece, which separates as a sequestrum, and then the bone scars over, leaving a rounded depression, much larger than the original spot, the surface of which is rather glazed and a little vascular, and the bone below it a good deal hardened. In well-marked specimens, these *annular* ulcers, as they are termed by Mr. Paget (fig. 587), look very characteristic, but in less advanced cases, especially before the surrounding trench has formed, or again at a late period when cicatrization has

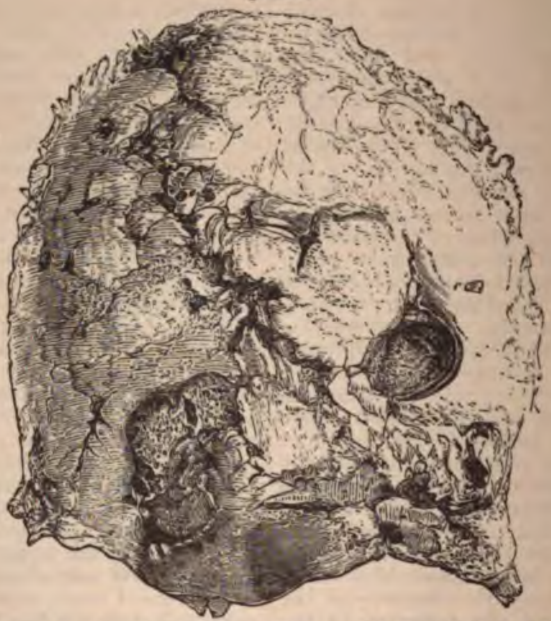
Fig. 587.



Syphilitic ulceration of the annular variety. (Museum of the Royal College of Surgeons, No. 635.)

obliterated some of the more distinctive characters of the ulcers, it seems impossible to distinguish it from a scrofulous or other lesion. The other characteristic form of syphilitic ulceration is the *tuberculated* (fig. 588), which appears to commence by a tubercular thickening of the external wall of the bone, recalling the syphilitic tubercle so common on the skin of the face, etc., and due not to periosteal deposit, but to chronic inflammation of the compact tissue itself. This inflamed

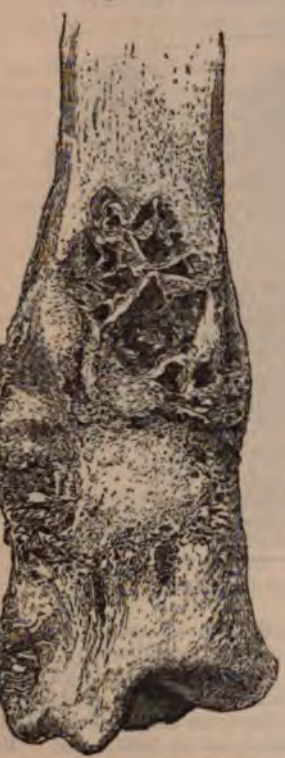
Fig. 588.



Syphilitic ulceration of the tuberculated variety. (Museum of the Royal College of Surgeons, No. 632.)

bone soon becomes dotted over with numerous little pits or depressions, which coalesce and form ulcers, usually oval or round, penetrating deeply into the interior of the bone. Besides these, Mr. Paget has described a third form of syphilitic ulceration, the *reticulated* (fig. 589) in which the disease appears first to show itself in the form of a network of periosteal deposit, which is liable to perforation by ulcers subsequently forming and assuming the annular type, of which latter, therefore, the above may be regarded as a variety. Of the two kinds of syphilitic ulcer, the annular appears to me the more characteristic; but I do not believe that either is so distinctive of the disease as to enable us, with anything like certainty, to infer the previous constitutional affection from examination of the affected bone; nay, I have known pathologists of the greatest experience refuted in such attempts by the subsequent discovery of the history of the preparation.

Fig. 589.



Syphilitic ulceration of the reticulated variety. (Museum of the Royal College of Surgeons, No. 630.)

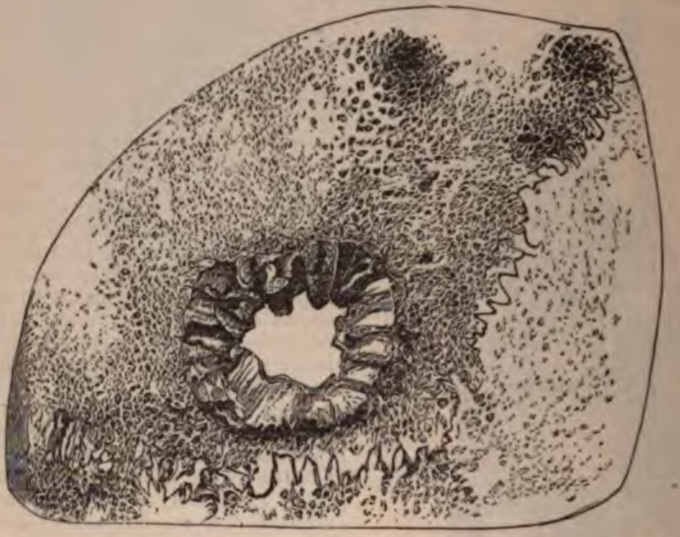
The accompanying figures represent characteristic examples of these various forms of syphilitic ulcer; and by comparing them with those of simple, strumous, rheumatic, and malignant ulceration, which will be found at pp. 135, 165, 183, the reader will be enabled to see at a glance much better than by verbal description, the differences of these affections as shown on the macerated bone.

Any of these forms of syphilitic ulceration may affect the bone so deeply as to penetrate its whole thickness. Thus in the Museum of St. Bartholomew's Hospital is a specimen (A 34) of a clavicle in which the bone has given way (probably after death) in consequence of penetrating ulceration attributed to syphilis. Spontaneous fracture of a long bone, however, from penetration by a syphilitic ulcer, is extremely rare; while penetration of a flat bone, especially of the cranium, is still a pretty frequent circumstance, and used to be an ordinary result of syphilis. In the greater number of such cases no serious mischief follows; the dura mater is exposed on the separation of the necrosed central part of the ulcer, but soon gets covered over, so that its pulsations are no longer visible, and in a little while the gap will be filled up by fibrous tissue. In rare cases, however, pressure upon the brain is produced either by matter confined between the skull and dura mater, or by ulceration laying open a branch of the middle meningeal artery and causing hemorrhage.

[There is, beside these forms of syphilitic bone-disease, a class of interesting cases which occur in the bones of young children with inherited syphilis. These cases have only recently been carefully studied, and for our knowledge of them we are chiefly indebted to Wegner, Parrott, and R. W. Taylor. Three chief forms of the disease have been described, viz., enlargement of epiphyseal ends of long bones, periosteal swellings or nodes on the flat bones, and a general osteitis of the phalanges of the hand or foot, and sometimes of the other bones of the hand or foot. The most common of all is the enlargement of the lower end of radius and ulna. This affection is seen in children from birth to several months old. It is slow and usually painless in its progress, sometimes going on to ulceration of the integuments, and not unfrequently to separation of the bone at the epiphyseal junction. Other long bones are affected in the same way, but less commonly. On the flat bones the swelling is in the form of a flattened node, there being one and sometimes many tumors on the external surface of the cranium. In the bones of the hand, the phalanx, for example, is thickened and enlarged by a rather firm swelling, which sometimes ulcerates superficially, and is also attended with destruction of bone-tissue so considerable as to leave behind it great deformity, if not carefully watched during the cure.

The pathology of all these cases seems to be uniform. It consists in one of those modifications of the process of inflammation so common in the diathetic conditions, in which the actions are arrested at a certain point, and have not the energy to carry them rapidly through the usual stages. The condition of cell-proliferation alone seems to be the feature of the earlier stages, with liquefaction and disintegration in the later. The periosteum is always thickened and inflamed in the diseased region. The minute pathological features of the disease have been carefully investigated by Wegner, Waldeyer, Parrott, and by R. W. Taylor, of New York, whose book on this subject is one of the best and most complete that has been published. The treatment which Dr. Taylor considers most generally useful is the mixed treatment as it is called, he giving bichloride of mercury and iodide of potassium in small doses for long periods of time.]

Fig. 590.



Penetrating syphilitic ulcer. (Museum of the Royal College of Surgeons, No. 636.)

Treatment.—The treatment of constitutional syphilis has been already described, and it has been shown that at one period or other of the disease a prolonged and sufficient exhibition of mercury will be necessary for its cure. To this general rule the affections of bone form no exception, for although some of them are usually found accompanied by so profound a cachexia, so complete a prostration of the whole system, that mercury is inadmissible, it will also be found that such affections do not admit of cure. Iodide of potassium often acts, however, upon the earlier affections of the bone and periosteum like a charm, and the symptoms soon disappear; but those whose experience in the treatment of syphilis is most extensive[1] believe that the improvement is not permanent, and that for the entire eradication of the constitutional affection a mild but prolonged course of mercury (for which the calomel vapor-bath is the most appropriate agent) ought to be insisted on. The local treatment of bone inflamed from syphilis presents several interesting questions. Nodes will usually be benefited by blisters, or if the bone seem to be more deeply affected, by the persevering use of mercurial ointment, strapping with the empl. hydr. cum ammoniaco, iodine paint, etc. But when the pain in the inflamed bone is constant and very distressing, it is quite justifiable to divide the periosteum by a free incision; and then, if nothing is found to account for the tension and to hold out a prospect of its relief, a trephine may be applied to the bone itself, and its medullary canal laid open.[1] If symptoms of cerebral disturbance make their appearance in the course of ulceration of the cranium, the application of the trephine has sometimes been successful in preserving life; but, on the other hand, it is not to be denied that it has sometimes produced or hastened death. The proverbial obscurity of all cranial affections ought, I think, to make us cautious in adopting so extreme a measure as trephining the skull, unless in a patient whose state is otherwise evidently hopeless.

---

[1] See vol. i., p. 226; Parker, op. cit., p. 289.

[1] Parker, op. cit., p. 283.

Epileptic convulsions, even with slight symptoms of paralysis, are hardly a sufficient indication for the operation; but the experience of Mr. H. Lee[1] has shown that in some cases the removal of the diseased bone has been followed by the healing of ulcers which had previously been obstinate; and it seems that the removal of the outer table only, when it is dead, and appears to be keeping up irritation, is a safe practice.

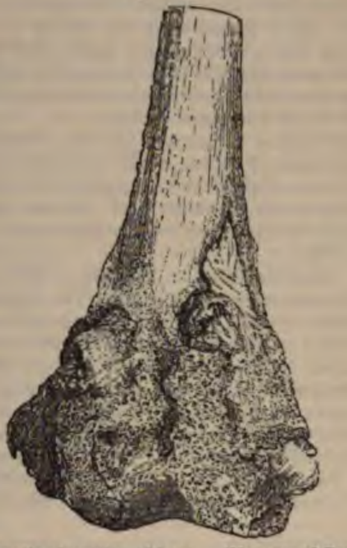
The treatment of fissures and defects of the palate from syphilitic necrosis will be found discussed in a subsequent essay.

Rheumatic and gouty affections of bone.—It is extremely difficult to be certain of the existence of any specific affection of bone due to the rheumatic diathesis. Rokitansky, in his "attempt to determine the characters of the constitutional affections of bone, particularly the inflammations and caries, by reference especially to the appearance of the bone after maceration,"[2] doubts "whether rheumatism gives rise to an inflammation that can be distinguished by any definite character of its products, or to any particular caries, however positively assertions be made on the point;" but there is no doubt that common osteitis is very generally produced by exposure to cold and wet, and other causes, which at the same time generate rheumatism, nor is there any reason whatever for questioning the universal opinion of persons of experience, that those who are the subjects of rheumatism are also those who are most prone to inflammation of the superficial bones, such as the skull, tibia, etc.

The disease now commonly called "chronic rheumatic arthritis" or "osteo-arthritis" is regarded by some authors of credit as originally a disease of the bone. In this work, however, it is considered as commencing in the soft tissues of the joint (see DISEASES OF THE JOINTS).

I would not be understood, however, to deny the existence of an affection which deserves to be called "rheumatic osteitis." The condition of the articulating extremities of the bones in cases of osteo-arthritis is very peculiar, and can hardly be explained by any theory except that of some constitutional peculiarity in the disease, since neither the age of the patient nor the mode of causation of the malady offers any constant features which can account for the singularity of the affection of the bone. That which is most characteristic in all those cases which appear to be rheumatic, is their very slow course, and the great length of time during which inflammation may be present without either caries or necrosis. In all rheumatic affections of the joints, and in many of those of the limbs, although it may be true that the complaint originates in the fibrous tissues, yet the bones will become involved if the disease lasts long enough; and in that case the principal features will be, in the shaft of a long bone, extensive stalactitic or foliaceous laminated deposit from the periosteum, and sclerosis of the superficial portions of the bone; the medullary canal and the deep cancellous tissue being usually, if not always, unaffected. In the Museum of the Royal College of Surgeons, Mr. Paget has classed some specimens[1] as "rheumatic ulceration," in which, along with these appearances on the shaft of the bone, ulceration is seen invading the newly-formed periosteal deposit. One of these preparations will be found represented in fig. 591. In any case, the occurrence of nodes, and of more or less inflammation of the wall of superficial bones in cases of rheumatism, is a sufficiently probable event; but it is a complication which must be treated on general principles. The nodes do not affect the limited extent and rounded outline of those due to syphilis, but are irregular swellings of the periosteum, involving a considerable extent of the surface, and probably some of the thickness of the bone.

Fig. 591.



Rheumatic ulceration of bone. (Museum of Royal College of Surgeons, No. 627.)

The most characteristic effects of rheumatism, however, are displayed upon the articulating extremities; but as this disease will be found fully described in the essay on DISEASES OF THE JOINTS, it will not be necessary to say much about it here.

[1] Proceedings of the Med.-Chir. Soc., vol. iii., p. 283.

[2] Path. Anat. (New Syd. Soc. Trans.), vol. iii., p. 202.

[1] Nos. 626, 627, 627 A.

The chief features which are distinctive of rheumatic inflammation of the bones are, the extensive deposit of bone in the fibrous structures around, the condensation and thinning of the shell of the bone, the rarefaction and partial absorption of its interior, and the consequent change of shape which parts containing much cancellous tissue, such as the articular heads and necks of long bones, suffer. In the articular disease the new bone is found, to a great extent, in the ligaments and other tissues distinct from the periosteum, and thus forms what Dr. Adams calls "additamentary bones," which have been so often mistaken for portions fractured off the bony prominences, near which they may be situated, and remaining ununited. I shall adduce some reasons for believing that many of the specimens in which portions of bone have been found near the shafts of long bones, but movable upon them, and which have been thought to be instances in which exostoses had been fractured at their base, may be of the same nature.

As to the treatment of the rheumatic affections of bone, nothing need be said here, since all that is necessary to add to the general treatment of osteitis will be found in the essay on DISEASES OF THE JOINTS.

I have nothing to say about the affections of the bones in gout. The deposit of lithate of soda is sometimes found in the interior of the bones in inveterate cases, as well as on their exterior; but its importance is quite secondary. Stromeyer[1] alludes to a case in which nearly all the bones of one side of the body were hypertrophied in a patient who had long suffered from gout; but no opportunity occurred of examining the bones affected.

Mollities ossium.—The peculiar condition of the bones which is known by the name of mollities ossium, or malacosteon, is one which is very rarely met with. In the female pelvis, as a cause of difficulty in parturition, it is less rare than under other circumstances, and demands the special attention of the obstetric surgeon, involving, as it does, some of the gravest questions which are to be solved by that branch of our art. These questions, however, which have reference to the altered relations between the deformed bones of the pelvis and their contents (especially the gravid uterus and fœtus), are not within the scope of the present work. We have only to consider the disease in its pathology and general surgical bearings.

The pathology of mollities is far from being satisfactorily established; and there can be little doubt that this has arisen, in great part at any rate, from the fact that authors have confounded several different conditions under the same name. Some, indeed, make no distinction between mollities and fragilitas ossium; while others regard mollities as an affection allied to, if not identical with, rickets.

The disease which appears best to deserve a separate description under the name of mollities, is marked by the following characteristics. Several bones are usually affected at the same time. The portions of bone attacked are uniformly softened throughout the whole extent of the disease. The disease, however, does not in all cases affect either the whole length or the whole thickness of the bone, and if the specimen be examined at an early period, the outer shell is often found to retain its natural consistence.[1] When the whole bone is affected, it can be readily bent, and resembles, in extreme cases, as Dr. Ormerod[2] remarks, rather a portion of fatty matter enclosed in a case of periosteum than a bone. If the cancellous tissue (in which the disease appears to originate) be examined, it is found that the cells are enlarged, sometimes to such an extent that the whole bone is expanded, and are filled with a peculiar reddish gelatiniform matter, in which, on microscopical examination, much fat and oil can be discovered, together with blood-discs. Besides these (which are the common products of any degenerative change), certain peculiar nucleolated nuclear bodies have been described by Mr. Dalrymple.[3] Instances of bones affected with mollities do, however, occur, in which the amount of fat is not greatly increased. Thus in a specimen in Guy's Hospital Museum (No. 1004^{55}), taken from a case reported by Mr. Solly, in the 27th volume of the Med.-Chir. Trans., it is said that the diseased tissue consisted simply of an organic matrix, with little earthy matter, and containing little fat. Cases like these show that it is impossible to describe mollities as simply a fatty degeneration. Degeneration of some sort is, however, always present; and as this advances, it involves the compact walls of the bone, and then the disease becomes for the first time recognizable, by the symptoms which will be immediately described. At a later period the whole bone is found to be involved, and becomes a mere bag of soft matter enclosed in the periosteum, which, perhaps, may be somewhat thickened, but it does not appear that any further destruction of the bone itself occurs. It is merely converted into a soft, generally oily, material, which crumbles away on maceration, but which seems capable of resisting absorption for an unlimited period during life.

[1] As in Dalrymple's case, referred to below.

[2] Brit. Med. Journal, Sept. 10, 1859.

[3] Dublin Quarterly Journal, 1846, p. 85; see also Path. Soc. Trans., 1846–7, p. 148. It is said that in bones affected with mollities, lactic acid and lactates are to be discovered, and that this lactic acid promotes the solution and absorption of the phosphate of lime. The fact, however, appears doubtful. See Drivon, Arch. gén. de Méd., 1867, vol. x., p. 608.

The symptoms of mollities are sufficiently striking in a well-marked case to attract immediate notice, however obscure may be the real nature of the constitutional affection. The patients are, it is said, usually females,[1] and generally past the middle period of life. Repeated pregnancy appears to act as an exciting cause of the disease, and may, perhaps, account for the greater proportion of females.

The disease appears to be, in some cases at least, hereditary. Thus, in the history of Dr. Ormerod's patient, referred to above, it is stated that both the son and daughter were subjects of the same affection. Sometimes pain is complained of in the affected bones for some time before the nature of the disease becomes manifest; in other cases, however, the deformity induced by gradual softening of the bones is the first symptom noticed. When this softening has proceeded far enough, the bone gives way gradually, if it has been equably and thoroughly softened, so as to yield, and become merely deformed; but if the softening has been confined to the internal part of the bone, and the thin outer shell has been left solid, and therefore brittle, spontaneous fracture (or, more correctly speaking, fracture from very slight causes) is liable to occur. The former class of cases, in which the bone bends without breaking, are those in which mollities is most characteristically marked, since spontaneous fracture preceded by pain in the bone is also a feature of malignant and other diseases of the osseous system. In such extreme cases of mollities, the limbs become distorted in the strangest way, so that the thighs have been known to bend till one of the feet touched the head; and from the softening of the vertebral column and bending of the limbs, the stature is very considerably diminished. The constitutional cachexia is often not very strongly marked, and patients will live in this condition for an indefinite period, bedridden from the weakness of their limbs, and the loss of the firm points from and to which the muscles act, but with sufficient mental and constitutional vigor. The cause of death appears generally to be simple exhaustion; or failure of vital powers, like what takes place in extreme old age (in fact some of these patients do not die till the extreme of life);[1] or sometimes functional disturbance, induced by the altered relations of the viscera, and the pressure to which, from various causes, they are subjected. Not unfrequently, however, the patient does not die of the disease at all, but, having lived under its influence for many years, is carried off by some totally different complaint.[2]

With these symptoms it is not surprising that this disease should have been claimed as merely a rarer form of several better-known affections of bone, to all of which it bears some resemblance, however little they may seem to bear to each other. Some authors[3] consider mollities to be merely fatty degeneration, or atrophy of bone; others regard it as rickets attacking the adult; while many class it with cancer. Now each of these opinions has a basis of probability, and it is very possible that many of the cases of so-called mollities might with greater propriety have been entitled "atrophy" of the bone. Of this, Mr. Curling's case appears to have been a good instance; and the difficulty which some authors have expressed in distinguishing between mollities and fragilitas ossium[4] appears to have arisen from their having compared together cases in which there was no real difference, and where the name mollities had been given to simple atrophy.

The connection between rickets and mollities appears, at first sight, a very close one, on account of the bending of the bones, and liability to fracture from slight causes, which characterize both. Some patients, also affected with undoubted mollities, have suffered in their youth from rickets.[1] Still, if we consider the question attentively, the differences between the two affections far exceed their resemblances. Rickets is an affection of early life, closely allied to scrofula in its causation and in its cure; it is peculiarly amenable to treatment; and under favorable circumstances the constitutional cachexia, which is its essence, readily disappears as the child grows. Mollities hardly ever makes its first appearance till after middle life; and, even in those cases where the patient has been rickety, not till long after the cachexia of that disease has subsided; it shows no alliance with scrofula, and is not amenable either to the remedies for that disease, or, as far as is known, to any other remedies, but pursues its career steadily, unaffected for good by any medical treatment.

---

[1] I do not find quite so great a disproportion between the sexes as is implied in the descriptions given by some authors. Of ten cases of true mollities taken at random, six were females and four males.

[1] See the cases mentioned in the Catalogue of Guy's Hospital Museum, Nos. 1044^{62}, 1098^{50}.

[2] Thus in Dr. Ramsbotham's case (Path. Soc. Trans., 1846–7, p. 148) the patient died of pneumonia, after suffering for more than six years from mollities.

[3] See Mr. Curling's paper in Med.-Chir. Trans., vol. xx., p. 356.

[4] It would be well if the term fragilitas ossium were allowed to become obsolete, since it only describes a symptom common to several affections.

In the latter particular, as in several of its other features, it bears a far stronger resemblance to cancer. In fact there can be little hesitation in classing some specimens preserved in museums as mollities under the head of diffused cancer; and, conversely, in recorded cases of cancer, some of the bones have been found in a state closely resembling, if not identical with, mollities.

Thus in a case of secondary cancer in the spine and other parts, after removal of scirrhus of the breast, related by Mr. Cæsar Hawkins,[2] it is noted that "the centre of the neck appeared a little sunk forward, as if the upper vertebræ had been depressed in that position;" and the anatomy of the affected bone is thus described: "The body of the fifth cervical vertebra was very irregular on its surface, and was softened throughout, with much enlargement of the cells of the cancelli, which were filled with a sanguineous pulpy fluid; the two adjoining vertebræ showed a lesser degree of the same morbid structure."

But, allowing that many of the recorded cases of mollities may be referred to simple atrophy, and some of the others to cancer, there can still be no doubt of the existence of an independent disease to which that name is peculiarly appropriate.

In one such case recorded by Dr. Bence Jones,[1] the leading feature was the peculiar condition of the urine. This attracted attention, together with the state of the patient's general health, long before any alteration in the bones was apparent; in fact, no alteration in them was discovered till after death. The peculiar substance contained in the urine appears to have been closely allied to albumen. Dr. Bence Jones's conclusions on this subject may be quoted here: "66.97 parts of this hydrated deutoxide of albumen were passing out of the body in every 1000 parts of urine. Hence, therefore, there was as much of this peculiar albuminous substance in the urine as there is of ordinary albumen in healthy blood. So far, then, as the albumen is concerned, each ounce of urine passed was equivalent to an ounce of blood lost. The peculiar characteristic of this hydrated deutoxide of albumen was its solubility in boiling water, and the precipitate with nitric acid being dissolved by heat, and re-formed when cold. By this reaction a similar substance in small quantity may be detected in pus and in the secretion from the vesiculæ seminales. This substance must be again looked for in acute cases of mollities ossium. The reddening of the urine on the addition of nitric acid might perhaps lead to the re-discovery of it; when found, the presence of chlorine in the urine, of which there was a suspicion in the above case, should be a special subject of investigation, as it may lead not only to the explanation of the formation of this substance, but to the comprehension of the nature of the disease which affects the bones."

These cases, then, of what we may call true mollities, are distinguished both from atrophy and from cancer by special characters: from simple atrophy by the existence of vitiated secretion, proving the affection of the constitution, and by the presence in the affected bone of special morbid elements; although the latter difference can hardly be appreciated during life, except in those rare instances where the bones are swollen. From cancer they are distinguished by the strict limitation of the morbid product to the affected bones, and by the different progress of the constitutional affection; since the patient, if he dies of the disease at all, dies of the exhaustion produced by vitiated secretion, or from the effects of mechanical interference with the viscera; not, as in extensive formation of cancer, from perverted nutrition, still less from transference of disease to remote organs.

Our knowledge of the true pathology of this complaint is as yet quite deficient, and so it follows that no means of treating it are known. The patient's strength must be supported, and he must be guarded from all exertions and shocks. If bedridden, his position must be accommodated to the shape of his limbs, so as to correct, if possible, the existing deformity by gradual traction, and to prevent any greater distortion. The fractures which occur in these cases are sometimes excessively numerous. Dr. Ormerod's patient had "at one and the same time no fewer than seven fractures of different bones." Yet in this case the fractures used to unite with the same readiness as they do in rickety bones.

---

[1] This was the case with Dr. Ormerod's patient above referred to.

[2] Med.-Chir. Trans., vol. xxiv., p. 45. See also a case of cancer of the bones after scirrhus of the breast, described by the author in Path. Soc. Trans., vol. xi., p. 219, in which some of the ribs were perfectly flexible. In examining a case of well-marked cancer of the pelvis, I have found a condition of the innominate bone bearing an almost equally close resemblance to mollities.

[1] Phil. Trans., vol. lxvi., p. 55. This is the same case as Mr. Dalrymple's, already referred to—the paper in the Philosophical Transactions containing the account of the peculiar substance found in the urine.

Many of the cases are hardly subjects for treatment, since the disease in the bones and the distortion of the limbs has advanced to an unmanageable extent before the patient is seen; and it would be scarcely desirable, even if it were possible, to protract the course of a painless but inevitable decay.

Cancer in bone.—All forms of malignant disease are met with in the bones, but the encephaloid, or medullary, is by far the most common.[1] Osteoid cancer is almost confined to the bones as a primary disease, although a very few cases are on record in which it has been found in the soft parts, without any known cancerous affections of the bones.[2] Cancer in bone may be either a primary disease, or secondary on cancer in some other, and usually a remote organ.

[Modern investigation has added much to our knowledge of the true nature of what is called malignant disease, both in the bones and in the soft parts. It has long been agreed by pathologists that those tumors which show either local recurrence after complete removal, a disposition to spread into and to involve neighboring tissues, a disposition to involve the lymphatics, and particularly the lymphatic glands, or a tendency to appear in distant parts, either before or after removal, shall be classed as the malignant tumors. It has more recently become evident that these evil qualities are not all possessed by all the tumors that possess some of them, and that the tumors which do possess one or more of these bad features do not possess them all in an equal degree, and finally that several forms of tumors possess them only occasionally, and as it were accidentally. Hence has arisen the distinction, clinically proper enough, into malignant and semi-malignant tumors.

It has not yet, however, been possible to arrange these various growths in such a manner that a given anatomical shall correspond to an observed clinical character, or to deduce the clinical history from the ascertained anatomical structure, or on the other hand to predict, with any approach to certainty, from a recorded clinical history, what the microscope will reveal as to its histological characters. From this it must be manifest that we are not yet in a position to classify tumors, either on the anatomical or on the clinical basis, in such a way as to make the classification perfect for our practical guidance.

Nevertheless, much has been accomplished, and new and valuable light has been thrown upon many doubtful points, particularly in malignant affections of the bones. Thus it is now generally agreed to restrict the term cancer to those growths which are essentially epithelial, and usually alveolar. Thus restricted, the term cancer is found to correspond very nearly to the class of tumors which clinically show, in the most marked manner, all the features of malignancy, viz., local recurrence, local infection, glandular contamination, and generalization. As far as this proves to be true, it must be accepted as a considerable advance in our positive knowledge as to the nature and tendencies of these tumors. But still further it seems reasonable to believe that epithelial cancerous growth can only take place in parts which contain epithelium as an original anatomical element, and that therefore primary cancer cannot occur in bones, in no part of which is epithelium normally found. This view of the histogeny of primary cancer is strongly stated by Prof. Lücke, of Strasburg. He says, "you know that the bones are in no way connected with the outer and inner blastodermic membranes, you can affirm therefore that no primary tumor in bone can be epithelial in character, in short, that there is no such thing as a bone-cancer." He goes on further to say that there are cases in which the primary tumor may occur in those bones which are covered by mucous membrane, the disease commencing in the epithelium of this membrane and extending into the bone. He also acknowledges that where the skin covering a bone becomes cancerous, it may involve the bone in the primary growth. These cases, he says, are rare, and are only apparent, not real, exceptions to his general law, for though the bone may form the chief part of the primary tumor, yet the origin of the disease has not been in the bone, but in the skin or mucous membrane covering it, and when, in any given case, the presence of epithelium can be shown to be impossible, the bone-tumor is not a cancer.

---

[1] In the notes of fifty cases of malignant disease of the bones which I happen to have by me, thirty-five are classed as encephaloid, four as osteoid, four as scirrhus, three as epithelial, one as areolar or colloid, one as melanosis of the periosteum, and the other two were tumors of doubtful nature and anomalous structure, but probably malignant. These notes, however, which are composed partly of extracts from books, partly of cases noted on account of interesting features, contain too large a percentage of rare forms of disease. This is evident in the number of cases of osteoid cancer.

[2] See Paget, Surg. Path., vol. ii., p. 496, ed. 1853.

Of course it is understood that these exclusive views as to bone-cancer have reference to primary cancer only. It is conceded that the bones are liable to secondary or metastatic invasion from any and every form of perfect cancer.

The views thus presented necessitate a change in our arrangement of the malignant diseases of bones; and all that has heretofore been considered primary cancer must be allotted to the class of the sarcomata. It becomes, therefore, a matter of great importance to give special attention to this, the most extensive, as well as the most fatal, of all the affections of the bones. The word, as now used, was first proposed by Virchow to denote a tumor originating from the middle or connective-tissue layer of the embryo, which had very much the appearance of granulation-substance, and was composed of undeveloped transitional cells, contained in a stroma varying in consistence from hyaline to almost fibrous, the proportion of cells to intercellular substance varying very greatly in the different classes into which sarcomata may be divided.

To this class of bone-tumors Dr. Samuel W. Gross, of Philadelphia, has devoted a great deal of careful examination and study, and has, in two papers recently published in the Am. Journ. of the Med. Sciences, given us the matured and well-considered results of this conscientious investigation. With regard to the relative frequency of the primary neoplasms of all kinds in the larger bones, he gives the first place to sarcoma, next osteoma; chondroma, osteoid chondroma, fibroma, and myxoma following in the order stated. His observations are confined to sarcomata growing in or on the long bones. Dr. Gross accepts the usual subdivisions into fibrous, myxomatous, lymphadenoid, alveolar, osseous, cystic, etc., but makes a more important division according to their point of departure. Thus he says "they may be separated into the peripheral,—periosteal or periosseous, and the central,—endosteal, intraosseous, or myelogenic; a division which is not only convenient as designating their seat, but which is also justified by the fact that, in general, they present marked differences in their histological construction, and are of different prognostic import." These two classes differ from one another in the fact that one has, and the other has not, a bony case or envelope which, when it exists, keeps pace with the growth of the tumor, rarely, even in the largest growths, being entirely absent. The periosteal tumors are covered with a fibrous or condensed areolar-tissue capsule, and never present any bony shell, and rarely even any superficial ossification of any kind. In shape the central tumors are apt to be spherical, the periosteal assume a great variety of forms. In their clinical history, central are greatly less malignant than peripheral growths. Taking the class of sarcomata as a whole, however, their malignity exceeds that of all other neoplasms except carcinoma of the soft parts; and this malignity is shown by all its usual features, with the exception of the contamination of lymphatic glands, which, as a rule, is not observed in the history of sarcoma. The generalization of sarcoma is one of its most marked features; 46 per cent. of the cases studied by Dr. Gross presenting this clinical feature, the metastatic tumors being found in the lungs, lymphatic glands, and in other parts of the osseous system; the secondary deposits being invariably of the same nature as the primary tumor.

Dr. Gross makes a subdivision of the two great classes of central and peripheral bone-growths according to their histological formation. Thus, of the periosteal class he makes three, viz.: 1st, the spindle-celled; 2d, the round-celled; 3d, the osteoid. And of the central also three, viz., 1st, round-celled; 2d, spindle-celled; 3d, giant-celled. He considers their degree of malignity to be in the order in which they are above named, and states that the periosteal forms are more malignant than the central by 43.5 per cent. Fortunately, the giant-celled, which is the least malignant, is also the most common, 42 per cent. of the whole number belonging to this class. The seat of these tumors in the long bones is by marked preference in the femur and tibia. They are rather more common in males than in females; by far the larger number occur before the age of thirty; and in nearly one-half of the cases studied traumatism is assigned as a cause.

Of these classes, by far the largest is the last mentioned, viz., the giant-celled sarcomata. This form of bone-tumor, first carefully studied by Lebert, afterwards more clearly described by Robin, and still later almost photographed by Eugene Nélaton in his Thése sur les Tumeurs a Myeloplaxes, corresponds exactly to the disease which Mr. Paget has introduced to English students as the myeloid or marrow-like tumor. This term myeloid, introduced by Mr. Paget, was selected by him because he considered that some of its characteristic cells were identical with those which normally exist in the marrow of young animals; and from this, perhaps somewhat strained homology, he inferred its essential benignity. Experience has somewhat chastened Mr. Paget's hopeful views, and it is now generally conceded that while a large proportion of these myeloid growths are to be fairly considered benign, a certain smaller proportion, say about one-quarter, show all the features of the deepest malignancy.

Under the microscope the structure of the giant-celled sarcoma is found to be "a stroma of spindle and round cells, but particularly the former, in which the characteristic multi-nucleated cells are embedded, with the intervention, usually, of little, if any, visible intercellular substance." . . . . "The giant cells themselves are made up of finely granular protoplasm, in which many round or ovoid nuclei are contained; but they differ from them (the normal marrow cell) in their relatively large size, sometimes reaching the enormous diameter of $\frac{1}{100}''$, or even $\frac{1}{80}''$, in the greater number and clearness of their nuclei, which are rendered more apparent by the addition of acetic acid, and in the variety and oddity of their forms, which it is impossible to describe. The contour of the cells seems to be influenced by the density of the intercellular substance, being irregularly spherical, ovoid, or lobulated when the latter is soft, and provided with numerous filiform, branched, or clavated processes, through which contiguous cells are occasionally united, when it is fibroid, in consequence of the protoplasm extending itself into the interstices of the fibrillæ. They also not unfrequently present a reddish-brown discoloration, to which the peculiar tint of the tumor, of which they form a part, is in some degree due."

Much difference of opinion has existed among pathologists, as to the derivation of these peculiar bodies, some believing them to originate from the normal medullary cells, which they resemble, others that they are modified bone cells, others regarding them as derived from the endothelial cells of the vessels; and some excellent observers holding views still different from all these. Dr. Gross, without considering the question as settled, inclines to the belief that they are "liberated and hypertrophied bone-cells," and he supports his view by some very ingenious considerations derived from the gross appearance and history of myeloid tumors.

The surface of the giant-celled growth, in the long bones, is usually smooth, and their shape spherical or ovoid. Their capsule is usually very distinct and firm, isolating them from surrounding tissues, and is composed of a shell of bone which is the original compact tissue expanded over the growing tumor. This bony shell is not always complete, the osseous deposits being wanting in many instances at various points, leaving the capsule composed at those points of a membranous expansion only.

On section the naked-eye appearances are commonly characteristic. The cut surface presents a smooth, glistening, juicy appearance, and a consistence which varies between a firm fish flesh and a soft pulp. Ordinarily not very vascular, in a few instances they are so abundantly provided with large vessels that distinct pulsation is received from them. The most striking feature, however, is the color, which is usually of a chocolate brown or of a maroon shade, somewhat like that of the splenic pulp. The color varies in depth and hue in different parts of the same tumor, and in different specimens presents also gradations of red up to pink. Some points are yellowish, and sometimes the whole tumor has a grayish tint.

These tumors are liable to a fatty degeneration, which, according to its stage of advancement, produces softening of the mass, and which is generally marked by a yellow coloration of the cut surface. Cysts are also found of varying size, and filled with a fluid, sometimes clear, sometimes discolored, with varying shades of red down to a dark reddish-brown. The vascularity of these tumors is occasionally very great, the vessels being dilated, tortuous, thin-walled, and often communicating with extravascular spaces like the structure of the corpora cavernosa. The pulsating tumors of bone almost invariably belong to the giant-celled class.

One very interesting and important feature which Dr. Gross has brought out by his investigations, is the relation of calcification and ossification to the malignity of the tumor in which they occur. He has found that in the majority of cases which present decided indications of malignity, this change has taken place, so that the mere fact of ossification is prima facie evidence of malignity, and its absence a favorable prognostic sign. The change is usually one of calcification rather than ossification, true bone not often being formed. This statement does not include the outer shell which covers and limits the tumor, but refers to interstitial deposits only. Statistics are given which very clearly show the rates of mortality from this form of disease, and the following conclusions are reached, which are presented in the author's own words.

"From the foregoing considerations it will be seen that about 23 per cent. of all cases of myeloid tumors are malignant, and that the degree of malignity may be graded in accordance with the existence or absence of calcareous or osseous deposits, since these were found in the original tumor in four of the five cases of metastasis. Further, it will be observed that the osteoid myeloid tumors are not absolutely malignant, as 43 per cent., or 3 out of 7 patients, remained well several years after their removal. Finally, in this connection it may be stated that of 15 examples of giant-celled sarcoma, in which calcification or ossification is not noted, only one was characterized by secondary growths. Hence the prognosis of the latter is as favorable as is the prognosis of some other neoplasms which are considered to be of an innocent nature."

The growth of giant-celled sarcoma varies greatly in regard to its rapidity, some cases growing very fast, and in others characterized by extremely slow growth. As a rule these grow more slowly than the other varieties of sarcoma of the long bones. The growth is sometimes arrested, as in a case reported by Mr. Hutchinson, in which a tumor of the head of the humerus ceased to grow for four years, and then resumed its activity. Occasionally they disappear altogether, as in a case mentioned by Mr. Paget, in which after the removal of a myeloid tumor of one side of the upper jaw, a smaller tumor of the opposite side gradually subsided and finally disappeared, the patient remaining well when last heard from. A case of partial disappearance occurred in a patient in the New York Hospital, whose thigh was amputated for an enormous tumor of the lower half of the femur which had been growing four months. The tumor, on examination, was pronounced to be encephaloid cancer, according to the views then prevailing (1856). In six months' time the disease returned in the skull, in the clavicle, and in several of the ribs. At one time a note is made, "The swelling on the clavicle has disappeared. The large tumor of the head is also subsiding." Two months later it is stated, "The tumors on the head are gaining a formidable size. That on the clavicle at one time almost entirely disappeared; which was also the case with the swellings on the ribs. The tumors on the head, after their first partial subsidence, steadily but slowly increased." The complete history of the case clearly indicates the tumors to have been of a sarcomatous character.

The relations of giant-celled sarcoma to the lymphatic glands is important and interesting. As a rule the glands are not affected in any part of the progress of the growth. In the few cases noted in which the glands were enlarged, in most the enlargement has been due to irritation, as evidenced by their disappearance after successful operation, or as shown by microscopic examination revealing no specific elements. "The absence of sarcomatous elements from the glands submitted to minute inspection; their diminution or disappearance after operation, the non-occurrence of periadenitis, through which they remain isolable, and unattached to the connective-tissue in which they are embedded; their freedom from ulceration, and their non-involvement in four other examples of general dissemination of the disease, are facts that lead to the conclusion that, in giant-celled sarcoma, glandular enlargement is the effect of irritation and not of specific infiltration, and that systemic infection takes place through the vascular, and not through the lymphatic system." The value of these observations in diagnosis must be evident.

The duration of the disease is so varied in different cases that no very reliable averages can yet be given. Among those who survived operation, however, Dr. Gross gives the average from the first observation of the disease to the date of record as about 55 months, or a little more than four years and a half; the majority of the patients being still alive. In reference to the period of the disease, early operations are not proved to be more successful than delayed ones. Rather the statistics show that the chance of life is better when a long period has elapsed before operation. This, however, is doubtless due to the fact that it is in the slow growing tumors that operation is most likely to be postponed, while in those growing rapidly it must necessarily take place at an early date. Rapidity of growth therefore is probably a more important factor in prognosis than promptness in operation.

These giant-celled sarcomata are the tumors which most frequently present the feature of pulsation. It occurs in about one-fifth of the cases, and is so rare in any other form of neoplasm, that a strong evidence as to the nature of a tumor may be derived from the mere fact of its pulsation. The few instances where pulsation existed in other than giant-celled sarcoma, were cases in which the tumor was a sarcoma, and a central sarcoma, but differed simply in not having the characteristic cells. The diagnosis therefore in every case of pulsating tumor is positive as to its being a central sarcoma, extremely probable that it is a giant-celled sarcoma.

The diagnostic indications are thus summarized by Dr. Gross: "A large, immovable, spherical, slowly growing, probably painful, and possibly pulsating, tumor of varying degrees of consistence, occurring in the articular extremity of a long bone, between the fifth and fortieth years, or at about the twenty-eighth year, unattended by changes in the integuments, or by the enlargement of the subcutaneous veins and lymphatic glands, and not marked by impairment of the general health, may be pronounced to be a giant-celled sarcoma."

2. Central spindle-celled sarcomata identical with the fibroplastic tumor of Lebert, the recurrent fibroid of Paget, and with the encephaloid cancer of many authors, are, next to giant-celled sarcomata, the most common in their occurrence. They are composed essentially of the well-known spindle-cells packed closely together, but lying orderly side by side, and the taper extremities dovetailing into one another so as to form a very uniform tissue, held together by a rather limited but varying amount of hyaline, slightly granular, or sometimes fibrillated, intercellular substance.

The tumors thus composed have very much the same gross appearances as the giant-celled variety, rarely, however, presenting the deep coloration which is so characteristic of that form. They are generally seated in the shafts of the long bones, and appear somewhat later in life than the giant-celled tumors, the average age at the time of their first discovery being thirty-six years. They grow more slowly, and there is no enlargement of lymphatic glands. They are malignant in their course in about 23 per cent. of the whole number of cases. Spontaneous fracture is surprisingly common, having occurred in 44 per cent. of all the cases. Pulsation existed in 12 per cent.

3. Central round-celled sarcoma. This class contains a great number of the cases described by authors as the encephaloid cancer of bone, and is characterized by structure made up of small, nearly equal sized, round cells held together by a small amount of intercellular tissue, through which vessels ramify, thus making the likeness to granulation-tissue upon which some authors may strongly insist. Departures from this typical form, however, are not uncommon. Thus we have a variety in which the cells are contained in an alveolar stroma, so distinct as to be with difficulty distinguished from the alveolation of true cancer. These tumors are extremely vascular, and very commonly pulsate. The excessive development of vessels has led Dr. Jaffé to consider these growths as essentially angiosarcomas. He also holds the view that the cellular elements of the tumor are the offspring of the nuclei of the walls of the vessels.

To the naked eye the section presents a general similarity to the spindle-celled tumors, but is more vascular and more liable to show ecchymotic spots or even cysts or cavities filled with blood. Some degree of ossific deposit occurs in about 17 per cent. Ulceration of skin and fungous protrusion occasionally, but very rarely, occur. Fractures are quite common. They occur in the shafts of the bones, in the proportion of 33 per cent. They are the most rapid in growth and the most steady in progress of any of the sarcomata. They are locally infectious in a higher degree, and more liable to generalization, than either of the other central sarcomata. Infection of glands is very unusual. It may therefore be said that "an immovable, bulky, rapidly growing, painful, soft, pulsating tumor, especially if seated on the shaft of a long bone, occurring at about the twenty-eighth year, and attended with fracture and possibly the protrusion of a fungous mass and enlargement of subcutaneous veins, but without discoloration of the skin, or involvement of lymphatic glands, may be said to be a central round-celled sarcoma."

The second division of sarcomata of the long bones which is made by Dr. Gross, "includes those which originate in the soft osteo-genetic layer of the periosteum in contradistinction to the tumors which are attached to the outer fibrous layer of that membrane; which should rather be considered as periosteal growths, or sarcomata developed in the tissues surrounding the bone, and affecting the periosteum secondarily. In the true peripheral sarcomata the tumor is seated between the bone and the periosteum, the latter of which is constantly regenerating itself to form a limiting capsule for it."

They present three forms, viz., the round-celled, the spindle-celled, and the osteoid.

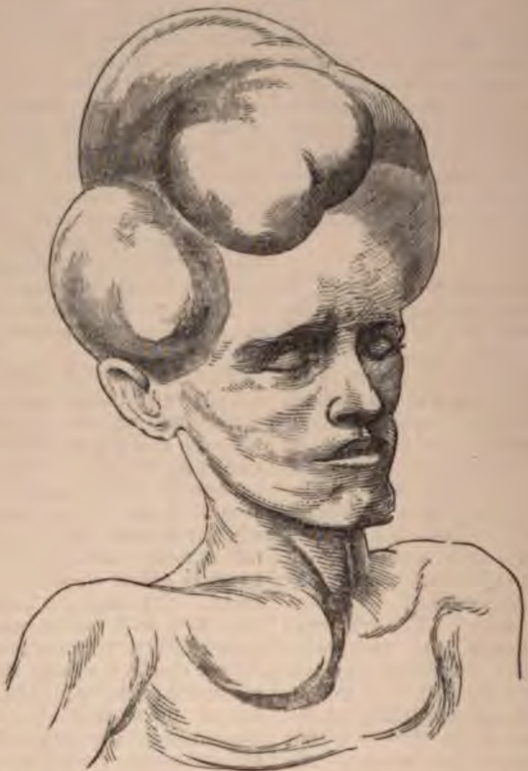
The round-celled sarcoma, in histological elements and arrangement, is identical with the central round-celled tumor already described. Clinically, they occur at a somewhat earlier age, and show malignant tendencies in a larger proportion of cases. The lymphatic glands are often infected; fracture is rare, and pulsation never occurs. The following summary is given of their characteristic features. "A rapidly increasing, painful, lobulated, soft, elastic, non-pulsating, pyriform or fusiform tumor, especially if seated on the shaft of a long bone, occurring at about the twenty-third year, and unaccompanied by fracture, but marked by discoloration of the skin, enlargement of the subcutaneous veins, involvement of the lymphatic glands, and elevation of temperature, may be safely ranked among the periosteal round-celled sarcomata."

2. The spindle-celled periosteal sarcomata occur at a much earlier age. They are most common on the epiphyses rather

than on the shaft of the bone. They very rarely are accompanied with fracture, but are almost uniformly malignant in their tendencies. Dr. Gross thus sums up their diagnostic features: "A firm, slowly growing, painful and non-pulsating tumor occurring at about the twenty-fourth year, and not attended with fracture, lymphatic involvement, or discoloration of the skin, but with possible enlargement of the subcutaneous veins, may be regarded as a spindle-celled periosteal sarcoma."

3. Osteoid Sarcoma. This class has arisen from the fact that a certain number of sarcomata show a remarkable tendency to extensive ossification or calcification, and that the recurrent and metastatic tumors show markedly the same tendency. Paget writes of these tumors as of osteoid cancer, and gives an excellent account of their clinical and microscopical features. Careful study shows that they do not possess the alveolation or, indeed, any of those features which it is now agreed to recognize as cancerous, and that they unequivocally belong among the sarcomata. Microscopically they are distinguished by a well-marked fibrous stroma, in which are found round cells and spindle cells in varying proportion, the fibrous intercellular substance becoming the seat of the calcific change. The ossified fibres usually radiate from the bone surface from which they spring, toward the free surface of the tumors. Sometimes the change is so complete that the whole mass is converted into almost solid bone; but in many cases the course of the original fibres is maintained in the process, so that on maceration the tumor shows a mass of fine spicula, running in various directions, and sometimes interweaving with each other, so as to make a complete framework or skeleton, on which the cellular elements had been supported during life.

Fig. 592.

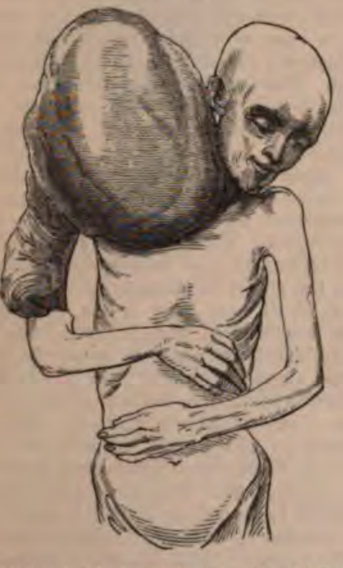


Periosteal osteoid sarcomata. (From a patient in the New York Hospital.)

The osteoid sarcoma is usually found to affect the epiphyses rather than the shafts of the long bones. They rarely pulsate, and do not often ulcerate or fungate. Their growth is apt to be rapid, but the lymphatics are not often affected. They are quite prone to the cartilaginous and myxomatous degenerations. They are apt to infect surrounding tissues, and extremely malignant in their behavior, about 65 per cent. dying with metastatic deposits, whether operated on or not. The clinical features may be given thus: "A hard, rapidly-growing, painful, and non-pulsating tumor, developed at about the twenty-second year, and unaccompanied by fracture, or discoloration of the skin, but attended possibly by enlargement of the superficial veins and lymphatic involvement, may be classed among the osteoid sarcomata."

All these forms of sarcoma, which have been studied by Dr. Gross in the long bones, do occur in other parts of the skeleton, notably in the jaws and cranial bones. In the jaw-bones we have a great many instances of the giant-celled sarcoma, and these often give most satisfactory results, while the small-celled and spindle-celled periosteal tumors are exceedingly apt to be fatal from metastasis. On the bones of the skull it seems probable that the most common form would be periosteal small-celled or osteoid sarcoma, though I have no statistics upon which to base such an opinion. Fig. 592 is taken from a patient who died in the New York Hospital from tumors which were then called encephaloid, but which we would now properly class as periosteal sarcomata. That they were osteoid in character is proved by their containing a very extensive framework of ossific or calcific tissue. The head of fig. 592 was macerated, and gave, as the record says, "the beautiful radiated feathery skeleton of soft friable bone-tissue." This we kept a long time in the museum, but it gradually fell away to a calcific powder. Fig. 593 is taken from a young girl, in whom the tumor attained the gigantic size well shown in the cut in about one year from its first appearance on the clavicle. All of these cases showed metastatic deposit in the lungs, liver, kidneys, and other internal organs.]

Fig. 593.



Periosteal osteoid sarcomata in a girl. (New York Hospital.)

As the general considerations applicable to malignant disease have been described in the essay on CANCER, it will only be necessary here to dwell on the peculiarities which are found in cancer when developed in the bones, with reference to its seat, manner of growth, and external appearances, and to endeavor to deduce the necessary inferences as to diagnosis and treatment.

With respect to its seat, no bone is exempt from the invasion of the disease, but some bones are far more liable than others; the long bones of the lower extremity taking the lead, and the femur being of all others most commonly attacked. Out of forty cases of primary cancer, twelve occurred in the femur, eight in the bones of the leg, five in the skull, three in the pelvis, and three in the spine. The others were single cases scattered about the various regions of the body. The neighborhood of the knee-joint is a very favorite seat of cancer; so that a soft tumor springing from the lower end of the femur or the head of the tibia is always viewed with much anxiety. Out of the above-mentioned twenty cases of cancer of the long bones of the lower limb, eleven are noted to have grown near the knee-joint.

The common kind of cancer in bone presents itself in three principal forms, viz., periosteal, interstitial, and infiltrated. The last is by far the least common. When carried to its extreme degree, the whole bone is softened by the distension of its cells with the material of soft cancer, leading to partial or complete absorption of the cancelli, and general disintegration of the bone. In this condition it forms one of the affections of bone which are included under the name "mollities ossium," under which head it has been referred to above. The periosteal form of cancer appears to be the more common in the long bones, while the interstitial is certainly the one more usually met with in the flat bones, such as the skull and pelvis, and in the joint-ends. The interstitial form is found in the shape of nodules of various, but usually small, size, scattered about the cancellous tissue. They are whitish in color when small and recently deposited, and generally give out a creamy juice under pressure, exhibiting the various cell-forms usually met with in the juice of malignant tumors. In the harder kind of these nodules, following scirrhous cancer in the breast (and to which the designation "scirrhus of the bones," used by some writers, applies, while others call them "hard encephaloid"), I have sometimes been unable to recognize any cancer-juice, or any cell-structure characteristic of cancer.[1] This interstitial deposit of cancer is productive of constant and wearing pain in the part, very frequently followed, in a long bone, by fracture on some slight injury or even muscular exertion. After some time, during which, if fracture has taken place, it may have consolidated, a tumor makes its appearance. The disease, having overcome the resistance of the periosteum, now grows rapidly. On dissection, a large mass of soft cancer is found, in which the periosteal envelope of the tumor may or may not be recognizable, and which springs from the bone by a narrower base, while it generally extends further in the cancellous tissue, or to a still greater extent in the medullary canal. In rarer cases, several separate nodules are found scattered about the cancellous tissue. The bone in the neighborhood of the cancerous deposit is often thickened,[2] sometimes to an extent that can be appreciated by external examination.

The accidental peculiarities of shape and arrangement in the various specimens of interstitial deposit of cancer have given rise to different terms, which having now lost some of their significance, ought to be, and have very generally been, allowed to become obsolete. Thus, when such a deposit in the articular end of a bone grows into a number of cancelli in different directions, the whole of the head of the bone becomes enlarged, forming a sort of multilocular cyst, the spaces of which are filled with the tumor, and the surrounding part of the bone a good deal consolidated. Such a swelling has been called the *malignant exostosis*. In other cases the soft tumor expands the outer layer of the bone uniformly, without producing fracture, and thus a swelling is formed, the wall of which crackles under the finger. This was called a *spina ventosa*.

In the periosteal form, the tumor makes its appearance sooner and grows more rapidly than in the interstitial. The subjacent bone is generally quite unaffected, and a section of the disease shows a ring of healthy bone surrounded by a radiating mass of malignant substance. The periosteum appears in some cases to have degenerated and become converted into the structure of the tumor; in others, it may be traced over the tumor, which then seems to grow between the bone and periosteum.[1] In this form of the disease there is a strong tendency to ossification, so that, after maceration, a large quantity of irregular bony deposit is left on the surface of the bone, forming very often a coral-like mass, with some approach to a spiral arrangement of its laminæ. These specimens were often described by the older writers as periosteal exostoses, their true nature being overlooked in consequence of the bone not having been examined till after maceration.

Cancer in bones is sometimes said to be a less rapidly fatal disease than in the soft parts, and perhaps if we compare it (as would seem most correct) with the average duration of *soft* cancer in the soft parts, this may be so; but the difference is not very marked. In twenty-eight of the cases contained in my notes the disease was followed till the patient's death from its commencement, with such approach to accuracy as is possible in these circumstances. In twelve of them death took place in less than a year (in five in less than half a year) after the first symptoms were noticed by the patient, and ten of the others died within the second year. In two only of the remaining cases was the disease protracted much beyond the usual period of duration of cancer, but neither were cases of encephaloid cancer; one, a case of colloid, might possibly be erroneously classed among malignant diseases. The true encephaloid cancer, then, in the bones, as in other parts, is more rapidly fatal than scirrhus, although its progress in the bone may be somewhat less rapid than elsewhere. But besides the encephaloid, all other forms may in exceptional cases be met with. Some pathologists, indeed, deny the existence of scirrhus in the bones, preferring to class the small hard nodules found in the spine, skull, and long bones, secondarily after scirrhus of the breast, and more rarely after scirrhus of other parts, as "hard encephaloid." The difference in nomenclature is a matter of no importance. Hard cancer, indeed, when deposited in the bones, cannot of course draw to itself the neighboring parts and thus reduce the volume of the organ in which it is placed, so that it is destitute of that puckering so characteristic of scirrhus of the breast. But in other respects it seems identical. The small irregular lump, creaking under the knife, emitting a very scanty juice, and presenting under the microscope, besides a good deal of common fibrous tissue, only small nuclear bodies, and those perhaps in no very large proportion, bears a sufficiently close resemblance to scirrhus in other parts to deserve the same name, more especially when only another product of the selfsame disease. Epithelial cancer attacks bones usually in the course of a cancerous ulceration of the soft parts which cover them, but scattered instances of its occurrence as a primary disease are on record. Thus in the Path. Soc. Transactions, ix., 358, will be found a description of this disease in the base of the skull. It presented the appearance of a mass of fibroid tissue, the meshes of which were filled with a yellow opaque and thick material, which could be squeezed out in the form of comedones, and consisted of a mass of epithelial scales. But these cases are of too rare occurrence to have much of practical importance; nor in the few scattered cases of colloid disease affecting bones with which I am acquainted, is there anything to throw light on the controversy as to the malignant or non-malignant nature of that affection. Melanosis affects bones very rarely, and probably is always a secondary formation; as in the case which has furnished the figure given above. The osteoid cancer has been sufficiently described elsewhere in this work (Vol. I., p. 290).

---

[1] This was so in a case reported in the Path. Soc. Trans., vol. xi., p. 220.

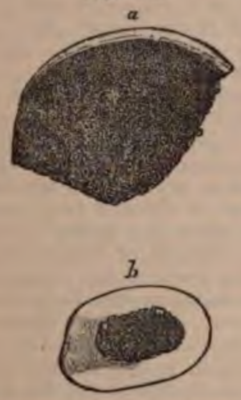
Fig. 594.



Melanotic cancer infiltrating the cancellous interior of the shafts of the long bones. Sections of the humerus:—*a*. A section taken somewhat parallel to the axis of the bone through its cancellous portion, showing the uniform infiltration of the cells with melanotic matter. *b*. A transverse section. The cortex of the bone is seen to be quite free in this section; but at other parts a few points of melanotic deposit were met with. The preparation was taken from the body of a woman who had been operated upon for the removal of a melanotic tumor. The disease returned in various parts of the body. The whole skin resembled that of a person who had long taken nitrate of silver, and melanotic matter was found both in the rete mucosum and in the derma. There was also extensive deposit in many of the internal organs. From a preparation (Series ii., No. 234) presented to the Museum of St. George's Hospital by Mr. Campbell de Morgan.

In the *diagnosis* of cancer of the bones two difficulties present themselves—*first*, to distinguish between a soft tumor and an abscess or other inflammatory affection; and *second*, to distinguish between a malignant and an innocent tumor.

The diagnosis between a tumor and an abscess is sometimes very difficult. The question occurs only, as far as I have seen, in the neighborhood of a joint; where also the doubt sometimes is, whether the swelling is not due to thickening of the synovial membrane. Generally speaking, however, the soft tumor is limited to one portion of the circumference of the bone, while disease of the synovial membrane would involve the whole circumference, although not necessarily equally prominent over the whole. Further, the chronic thickening of the synovial membrane will have been preceded by a long course of symptoms of disease in the joint, and these symptoms will probably have been more acute at some previous time; while the tumor will have commenced much more recently, at first without any symptoms, and the symptoms will have been more marked as the tumor got larger. Limited abscesses, also, in the thickness of the swelling, are common in the chronic synovial disease, while abscess is a rare complication in the course of a tumor, and then forms external to it and singly.

The following instance of the occurrence of abscess around a rapidly growing tumor, will illustrate the difficulty of the diagnosis in such a case. A young woman was admitted into St. George's Hospital under the care of Mr. Cæsar Hawkins, complaining of pain near the ankle; no diseased appearance then existed. Soon, however, a soft swelling made its appearance, fluctuation was detected, and an incision behind the internal malleolus gave exit to pus mixed with blood, and exposed a cavity which appeared to be that of an ordinary abscess. After a few days arterial hemorrhage came on, and soon became uncontrollable. Pulsation also became evident in the swelling. The incision was extended, and several pieces of soft, breaking down tissue escaped; the finger passed into a mass of fungous matter springing from the os calcis. After amputation the disease was seen to be a soft tumor, about the size of a walnut, connected by a broad base to the calcaneum, and surrounding the posterior tibial vessels. The artery showed a small perforation.

It is seldom, however, that such difficulty is experienced as in this case in forming the diagnosis; and if from the ambiguity of the symptoms, and the thickness or tension of the soft parts over the swelling, doubt is felt as to the presence of a soft solid or a collection of fluid, the introduction of a grooved needle will in most cases decide the question. Usually the lobulated surface of the tumor, and the healthy and uninflamed state of its coverings, suffice to distinguish it from an abscess.

The diagnosis between malignant and innocent tumors is often very difficult, and sometimes impossible. It is of most importance, and unfortunately is also of most difficulty, in those which grow around the lower end of the femur. Malignant and myeloid tumors here often bear the strongest resemblance to each other, so that the diagnosis in an early stage of the cancerous affection can be only conjectural. By a reference to the essay on TUMORS (Vol. I., p. 265) the reader will see that the points to which the surgeon is to direct his chief attention are: the length of time during which the tumor has existed without constitutional or glandular affection, the bulk to which it has attained, and the extent of its attachment to the bone, since myeloid disease is an affection of the cancellous ends, while encephaloid often surrounds the shaft to a considerable extent, forming a long oval tumor, like a great ferule. But it must be allowed that the diagnosis between these forms of disease can hardly be expected to be accurate, inasmuch as there is strong reason for believing that myeloid tumors are occasionally malignant. There are other tumors also which could hardly be distinguished from cancer until a long progress had proved their innocence. Such are the fibro-cystic, to be afterwards mentioned, and such may also be the case sometimes with enchondroma, and with the diffused osseous tumor. It is only, however, in the very early period of osteoid cancer that its malignancy is not a prominent feature. It grows rapidly, extends far along the bone, and soon affects both the constitutional powers and the absorbent system.[1]

In general, malignant tumors of bone may be known by their large size and rapid growth, their soft consistence, the unequal density of different parts, the large veins which ramify over them, the extent of their attachment to the bone, the frequent presence of large sanguineous cysts, the amount of pain by which their growth is attended and often preceded, and the rapid destruction of bone which they occasion. To these local symptoms the general symptoms of the constitutional affection may be superadded.

The treatment of cancer in all parts of the body resolves itself into the question of leaving it alone, or eradicating it. The only method of extirpating malignant disease of any bone, which is at all satisfactory, is by excising the tumor along with the whole thickness, at any rate, of the part of bone from which it springs. To remove the tumor from the surface of a bone, in the uncertainty which must always exist whether cancer has not also affected the interior, would be highly imprudent. Nor is this sufficient; for if the disease can be clearly made out to be cancerous, the whole limb, including the entire bone which is the seat of the disease, ought to be amputated. When the tumor is situated in the leg, this is a matter requiring comparatively little deliberation; the choice only lies between amputation of the leg and of the thigh, and the difference between one stump and another is of slight moment, compared to the risk of a return of malignant disease. But if the tumor affect, as it so commonly does, the lower end of the femur, the question becomes a grave one; since amputation at the hip-joint must be performed if the disease is clearly diagnosed as being cancerous. If there is a reasonable doubt whether the tumor be soft cancer or myeloid, or whether it be hard cancer or diffused bony tumor, undoubtedly the wisest course is to give the patient the benefit of that doubt, and to remove the limb at the lowest level at which the incisions can be carried clear of the tumor. Even if the disease should prove to be cancer, possibly the recurring disease may be in the cicatrix, and amputation of the stump at the hip-joint may prolong life. But so many cases are on record in which what has been supposed to be malignant disease in this part (and which in all the cases was most likely myeloid) has been completely arrested by amputation of the thigh, that it is only right to try the milder operation in cases not evidently cancerous.[1] In the forearm the character of the disease is usually better marked (as far as I have seen), or in dubious cases the alternative is not of much importance; nor in the humerus is the removal of the limb at the shoulder-joint by any means so formidable as in analogous operation on the lower limb.

---

[1] Two cases of osteoid cancer of the femur were in the surgical wards of St. George's Hospital about the same time. In one, although the affection was not of long standing (less than a year, I believe), the inguinal glands presented the characteristic bony hardness. In the other, the tumor, which was mixed with encephaloid, was growing rapidly, and contained a large cyst, the tension of which occasioned much pain, relieved by drawing off the fluid. Amputation at the hip was successfully performed by Mr. Tatum; but the disease recurred in the lungs, and proved fatal in about half a year.

[1] See Mr. Gray's paper in Med.-Chir. Trans., vol. xxxix., p. 121.

Hence in the upper limb the rule should be the reverse of that in the femur, viz., that in cases of doubt the entire limb ought to be removed.

What is the benefit of amputation in such cases as these? This is a question very difficult to determine, if the question be limited to the expectation of life. Scattered cases are met with here and there in which a disease apparently malignant has seemed to be checked after amputation; nay, where it has recurred after amputation, and then been checked by amputation higher up;[1] but these are rare exceptions. The disease may be expected to recur, and to prove fatal; and the operation must be defended rather on the grounds of humanity than of scientific indications, as affording relief from present suffering, and the chance of an interval of some months, perhaps even longer, of health, rather than as holding out much prospect of a radical cure of the complaint.

[There is so much that is uncertain in the results of operation in malignant tumors of bone, so much that belongs to the calculation of chances, that it would seem desirable, if possible, to arrive at some general rules which will at least serve as a guide to us in recommending or dissuading from an operation, and in announcing such a prognosis as may have in it at least some elements of probability.

1. It should be borne in mind that, however strongly statistics may indicate a favorable percentage of cures in any given form of bone-tumor, we are not yet in a position to pronounce positively in individual cases. Although our willingness to operate would very properly be determined by our judgment as to the class to which the tumor belongs, yet we are not at liberty to offer a confidence of permanent cure, even in cases we judge to be most promising. Remembering that the percentage of malignant cases varies from 12 to 70 in the different forms, it becomes us to give always a guarded prognosis, and in the bad forms a decidedly unfavorable one.

2. Want of completeness in the operation is a most disastrous feature. In the long bones, happily, we can usually make sure of a total ablation by amputation. In the bones of the face and of the skull, however, we cannot always be certain of the total removal of all diseased structure, and if this fact can be made evident, it militates very strongly against operation. There may be exceptional cases in which partial operation may be justified to secure relief from suffocation, or constant hemorrhage, or blood-poisoning from putrid discharges, but the rule must ever be not to operate where we cannot be sure of removing the whole diseased mass.

3. The operation itself, it must be remembered, involves a certain proportion of deaths, independent of the disease for which it is performed. This proportion varies in the two chief operations which are resorted to in bone-tumors, viz., amputation, and exsection of the jaws. It is not necessary to state here what statistics have pretty distinctly shown as to the mortality after these operations. It is enough to recognize this mortality of the operation itself as an important factor in the decision we arrive at, and in each case the proposed operation must be credited for its share in the risks the patient is about to assume. These three considerations embrace the chief objections to operation on general principles, but on the other hand we may claim—

1. That a certain percentage of those operated on do permanently recover. This percentage, very large in the giant-celled, becomes sadly reduced in the periosteal spindle-celled forms, but taking all cases together, gives such a percentage of recoveries as constitutes a fair warrant for operation in every case when, on other grounds, operation is justifiable.

2. There seems reason to believe that, even where permanent cure is not achieved, some prolongation of life is secured by operation. In carcinoma proper, in other parts than the bones, the prolongation of life by operation has been shown to be considerable. No one has, as far as I know, given full statistical statements on this point as to those patients with bone-tumors who do finally die of the disease, but as far as published statistics do go, they point decidedly to a lengthening of life by operation.

3. When, after removal, the disease returns, and finally destroys the patient, it returns most commonly in the internal organs. That existence is usually more supportable under the fatal progress of internal malignant disease, than it is under the too visible ravages of the external forms, seems to be pretty well ascertained. To say nothing of the fungous ulceration, the alarming hemorrhages, and the wasting discharge, we may easily believe that the frightful deformity of some of these immense growths (fig. 593), the sickening fetor of the discharge, as well as the heart-sickening sight of the flowing blood, all conspire to make a death from external malignant disease too dreadful to be described, while death from the same disease in the liver or lungs would present no features more distressing or more repulsive than from any of the usual fatal diseases of these organs. While, therefore, I would not claim that

---

[1] Path. Soc. Trans., vol. vi., p. 291.

this euthanasia ever is a reason for operation, I think it fair to say that when, for other reasons, an operation is justifiable, this also is to be taken into the account as rendering it desirable.

4. If the patient recover from the operation, there is a period of entire freedom from the disease. This may be short or long, but it is perfect while it lasts, and is almost always accompanied by a feeling of confidence on the part of the patient, that it will be permanent. This state of mental elation and hopefulness is in itself a great gain, though it be only temporary, and certainly fits the system better to resist the recurrence of the disease, if recur it must. Mr. Paget well remarks "when they are no longer sensible of their disease, there are few cancerous patients who will not entertain and enjoy the hope of long immunity, though it be most unreasonable and not encouraged."

Acting upon these principles we may advise an operation—

1st. In cases in which the disease can be certainly and entirely removed, as by amputation of a limb or by excection of the maxillæ.

2d. When there is no evidence of secondary deposit in any internal organ, and no general infection of the lymphatic glands.

3d. When true cancerous cachexia has not as yet declared itself.

4th. When the operation itself does not too seriously imperil the life we are aiming to prolong.

5th. When the tumor has been of slow growth from its beginning. Here we have reason to hope that the slowness which has characterized the growth of the tumor, will show itself in the long delay of its reappearance. Very rapidly-growing sarcomata are commonly very rapidly reproduced.

Lastly, our knowledge of the ultimate disposition of a given tumor must be so uncertain, though we may be enabled to arrange it accurately in the class to which its histology entitles it to belong, that it may often happen that we are performing a perfect and permanent cure, when we have only dared to promise a palliation.]

Pulsatile malignant tumor of bone, and osteo-aneurism.—A remarkable feature in malignant tumors of bone is the occasional occurrence of pulsation in them. This pulsation can sometimes be with difficulty distinguished from that of ordinary or sacculated aneurism. The resemblance also which these malignant tumors of bone sometimes bear to the aneurisms by anastomosis is so strong that they have been described as "aneurisms of bone,"[1] and have been believed to consist merely of a dilated vessel or vessels in the interior of an otherwise healthy bone. But it is now admitted that the great majority, at any rate, of these so-called "osteo-aneurisms" were really pulsatile malignant tumors. The resemblance to aneurism by anastomosis is in the highest degree perplexing when the pulsatile tumor occupies a situation where that disease is common, such as the scalp.

A woman applied at St. George's Hospital some years ago on account of a pulsating tumor on the vertex of the head. Mr. Prescott Hewett, under whose care she was placed, came to the conclusion that the disease was a malignant tumor of the skull, and dissuaded her from any operation. Being anxious, however, to have the tumor removed, she consulted another surgeon, who gave it as his opinion that the tumor was an aneurism by anastomosis, and might be extirpated. Mr. Prescott Hewett accordingly sought the advice of his colleagues, and after a careful examination they confirmed him in his original opinion, that the tumor was malignant and had perforated the cranium. He therefore declined to operate; and the woman was placed in another hospital, by the advice of the gentleman whom she had subsequently consulted, and who then attempted to excise the supposed vascular tumor. The original diagnosis, however, turned out to be correct, and it became necessary to give up the operation. Such cases as these show the difficulties which may be experienced in diagnosing the nature of such a tumor in the scalp; but it more frequently occurs that the pulsatile tumor of bone is situated on the course of some large artery,[1] and simulates an ordinary aneurism (see article ANEURISM, Vol. II., p. 339).

The anatomy of these tumors is as follows: they spring from the cancellous interior of the bone, expanding and eroding its external shell, until they burst out, frequently on both sides of the bone at once, forming lobulated masses, which sometimes attain a large size. On section they are seen to be red, of a fleshy consistence, and containing large spaces or cells filled with blood, from the pulsation of which the tumor derives its movements, and which must therefore communicate freely with the main arteries around, though the exact nature of that communication has not yet been demonstrated. The pulsation appears to depend on the resistance of the periosteum, which is often thickened. Hence when the periosteum is penetrated, the pulsation frequently disappears; as that of an aneurism will do when the sac has given way. The microscopical characters of soft cancers can be recognized in the structure forming the walls of the cells. Spicula of bone are often found mixed up with the malignant matter. The tumor frequently affects the large veins in the neighborhood, projecting into them, or even blocking them up; and several such tumors may exist together, or malignant disease of the ordinary encephaloid variety may be found in some other organ of the body (see the case quoted on p. 340, Vol. II).

---

[1] See especially a paper by Breschet, "Observations et Réflexions sur les Tumeurs sanguines d'un caractère équivoque, qui paraissent être des anévrismes des artères des os."

[1] Such tumours may, however, form in any bone with copious diploë. In the Edinb. Med. and Surg. Journ., Nov., 1860, p. 452, is an account of one which implicated the basilar process of the occipital bone and the first three cervical vertebræ.

The diagnosis of a pulsatile malignant tumor of bone is very easy in some cases, almost impossible in others. It is easy when the tumor springs from a superficial bone, lies away from the course of any large artery, and has no bruit; and still more so when other malignant tumors or symptoms of malignant disease are present; but where its connection with the bone is obscure by reason of the depth at which its base lies, when a large artery (which is generally the iliac, gluteal, or femoral) lies near its situation, when its pulsation is accompanied by bruit,[1] when the tumor is solitary and the general health unaffected,—it becomes a matter of the utmost difficulty.

Enough, however, has been said on this subject in the essay above referred to.

[Some assistance may be derived from considering the force of the expansion of the tumor at each beat of the heart. If we place the two hands on the opposite sides of a strongly pulsating aneurism, we shall find that not only do the opposed fingers recognize an expansion of the tumor at each contraction of the heart, but this expansion is found to take place with an amount of power which is surprising to those who do not think of its explanation, which is a purely mechanical one.

It is a well known law of hydrostatics, that when a small tube communicates with a large closed cavity containing fluid, the amount of force acting on the walls of that cavity will be estimated by multiplying the amount of pressure exercised by the fluid in the small tube, at its point of communication with the larger cavity, by the number of times the area of the small tube is contained in the area of the walls of the large cavity. Thus, if a tin or leaden tube of one square inch section communicates by a tight joint with a cask whose inner surface comprises five hundred square inches, and both are filled with water, the pressure in the tube will be according to the height at which the water stands in the tube. If we suppose this pressure in the tube to be one pound, then on the inside of the cask will be exerted a pressure of five hundred pounds, which will be proportionally increased for every pound of additional pressure in the tube. In this way a very moderate force exerted through the tube becomes an enormous force on the inner surface of the cask, which can easily be increased so as to burst the strongest barrel that can be made. This is the principle of the hydrostatic press, by which such amazing power can be developed; and it is also the principle by which the pressure of the blood on the inside of the walls of an aneurism may be calculated; due allowance being made for difference of physical conditions. This enormous force of expansive pulsation in an aneurism, which must be carefully distinguished from its extent, explains very satisfactorily the irresistible march of the disease, no barrier, be it ever so unyielding, and no tissue, be it ever so tough, being capable of resisting its relentless progress. It can also be appreciated more or less distinctly in every aneurism by careful examination, and can be relied on, when clearly made out, as very certainly distinguishing the pulsation of an aneurism proper from that of any other tumor.

In a case recently occurring in the New York Hospital of pulsating tumors in the left groin, a careful study of the entire group of symptoms, and of the history of the growth, left a reasonable doubt in all our minds as to whether the swelling was a tumor developing in the iliac bone, or whether it was an aneurism. The pulsation, however, though it was not very extensive, that is to say, did not separate the sides of the mass very widely, yet when firm compression was applied by the hands on each side of the growth, was so strong that I clearly perceived that the hands were thrust apart by a force which was entirely uncontrollable by any muscular power I could bring to bear upon it. This feature clearly and repeatedly made out in my own mind, decided the diagnosis in favor of aneurism, a decision which was amply justified by the perfect cure of the disease by the application of a ligature to the external iliac artery.

This sign has repeatedly proved itself trustworthy in my experience, though of course it must not be too blindly relied on. For example, in a case of unequivocal malignant tumor of the thigh, in the Roosevelt Hospital, the pulsation was so strongly expansile, that I fancied there must be some very large blood space communicating by small orifices with the arteries, but the autopsy did not prove my suspicion to be correct. The sign is most clear in large aneurisms with little or no stratified fibrin or coagula filling up the cavity, and is sometimes very indistinct where the aneurismal sac is very much occupied by solid substance.

---

[1] Cruveilhier (Anatomie pathologique, 1856, vol. ii., p. 901) relates a very interesting case in which an encephaloid pulsatile tumor, springing from the bones of the skull, presented so marked a thrill, and a sound so exactly resembling that of arterio-venous aneurism, that he was led into the belief that such was the nature of the tumor, until dissection revealed its true character.

The application of this mechanical principle in studying the pulsation of a tumor will often help us to a correct decision when the character of the pulsation, be it strong or weak, is well marked.

In cases where other tumors exist, or where the symptoms of constitutional cancer are present, no doubt can be felt as to the inefficacy of local treatment; the disease declares its malignancy by the same signs as cancer in other parts of the body, and its prognosis and treatment must be the same. But are there any pulsatile tumors of bone of a different kind, in which the surgeon can hold out a a hope that the excision of the tumor, or its consolidation by chemical agents, or by ligature of the artery which leads to it, will offer a reasonable hope of cure; or must the patient be sentenced to the hard alternative of death or amputation?

In the former edition of this work I expressed a strong doubt of the existence of the disease ordinarily described as "osteo-aneurism," and gave my reasons for pronouncing all the cases which had been published up to that time, insufficient to establish its reality.[1] A more satisfactory example has been published by Dr. Mapother in the Dublin Med. Press, February 4, 1863, p. 105. In this case there was a pulsating tumor of small size situated on the tibia, accompanied by a distinct thrill and slight bruit; but without any indication of disease in other parts of the osseous system or in the body generally. The diseased tissue was destroyed by two applications of the actual cautery, in doing which its vascular nature was clearly testified by the acute hemorrhage. No other morbid tissue was exposed by the opening which was made into the tumor; but there was, of course, no opportunity for anatomical examination. The wound healed perfectly, and I am told by Dr. Mapother that the patient remained in good health two and a half years afterwards.

Again, in the Path. Trans., vol. xix., p. 349, is the account by Mr. Bickersteth of a case where he amputated the leg on account of a pulsating tumor of the tibia, which "felt firm, but was slightly compressible, yielding to deep pressure, and giving a spongy feel to the finger, with an occasional sensation of crackling. The skin was free and sound. No bruit was audible." An incision was made into the tumor, which exposed a surface having all the appearance of malignant disease, and the leg was amputated under the idea that the tumor was cancerous. On examination of the tibia in front, it was found much expanded at its lower end, where a mere shell of bone remained, bending and crackling under the finger. Behind was a large oval tumor, five inches long by three broad, springing from the posterior and outer side of the expanded tibia, and running upwards from the lower end of that bone into the interosseous space, overlapping the fibula, but not connected with it. It had a distinct wall, and was divided into two parts by the tendons of the tibialis posticus and flexor longus digitorum, which ran in a groove or channel in the tumor, through nearly its whole length. The bulk of the tumor was found to consist of innumerable trabecular spaces; the fibrous bands composing which, as well as the walls of the tumor, were derived from the periosteum of the tibia. These spaces were filled with clotted blood. The part of the tumor external to the tibia was formed by two large sacs, filled with clotted blood. All parts of the tumor communicated with each other.[1] There was no admixture of cancerous matter; and the case appeared, both to Mr. Bickersteth and to the committee of the Pathological Society who examined it, to be a perfect example of aneurismal dilatation of the vascular spaces of the bone.

Mr. Bickersteth has had the kindness to inform me that he has seen the patient very lately, and that he remains perfectly well.

We may therefore allow that in some rare cases, pulsation has been noticed in innocent tumors situated on the long bones, and displaying no other recognizable structure except enlarged vessels. It seems also that pulsation has been recognized in a myeloid tumor;[2] and, as these tumors are usually innocent, it would follow that the mere presence of pulsation in a soft tumor of bone is not to be considered as a decisive proof of its malignancy. If, however, we allow these exceptions to the rule that pulsating tumors of bone are malignant, we must still admit that there is no reliable account of any such tumor connected with the skull or pelvis (those favorite seats of the disease) which was otherwise than cancerous.

---

[1] Such are Cruveilhier's case, Anat. Path., 1856, vol. ii., p. 901; Lallemand's, prefixed to Breschet's paper above quoted; Dupuytren's, in Leçons orales, vol. iii., p. 232; and I may add Capelletti's, as quoted in the Biennial Retrospect of the New Syd. Soc., for 1865–6, p. 249.

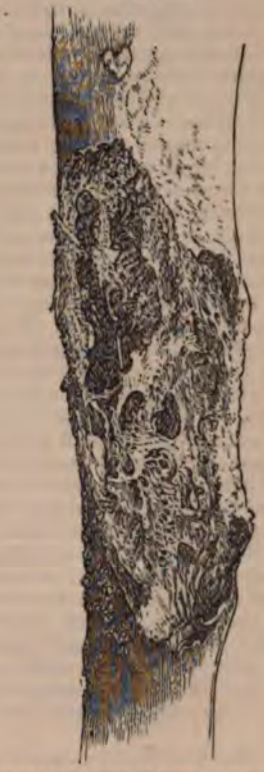
[2] Gray, "On Myeloid Tumors of Bone," Med.-Chir. Trans., vol. xxxix., p. 138.

If such are our views with respect to the nature of the pulsatile tumor of bone, our opinions as to the proper course of treatment cannot be doubtful. To tie a large artery is so very grave a measure, that it can only be justified by the clear prospect of impending fatal hemorrhage, or by the presence of an aneurismal tumor pressing upon important organs. In these pulsatile tumors, however, hemorrhage is rare, and only occurs late in the disease; nor are important parts often pressed upon, except in the cranium. If it be said that the growth of the tumor will be checked by the ligature of its nutrient vessel, the answer is, that this is by no means borne out by experience, and that even if its growth were checked, the disease would not therefore be cured; while the doubtful good to be derived from a very uncertain diminution in the bulk of the tumor is as nothing when compared to the frightful risk of tying a large artery in a subject probably already debilitated by the cancerous cachexia. In many of the recorded cases, the ligature of the main artery appears so far to have affected the tumor as to have checked its pulsation. But the pulsation, though a formidable symptom, is not an essential, and may not even be a constant, part of the disease. Thus Professor Miller relates[1] a case of pulsatile malignant tumor in the ham, which was at first mistaken for aneurism. The pulsation disappeared spontaneously, but returned after an exploratory puncture made in the tumor. Afterwards the pulsation varied, disappearing occasionally, and then recurring.

The purport, then, of all that has been noted as to the course and nature of this disease, and as to the effect of treatment, appears to justify the following conclusions: that in pulsatile tumors connected with the bones of the extremities, if the tumor be small and the other symptoms favorable, the surgeon is justified in treating the disease as an instance of the rare occurrence of osteo-aneurism, and endeavoring to extirpate it either by cutting away the portion of bone from which it springs, or (better) by caustics or the actual cautery; that if it be of large size, amputation should be recommended through or above the nearest joint, except in those connected with the lower end of the femur, where it may occasionally be advisable to amputate near the tumor; that the ligature of the main artery of the limb is unjustifiable; that in pulsatile tumors connected with the head, chest, or pelvis, no local measures ought, as a general rule, to be employed, but the disease should be treated as one of cancer; and finally, that the prognosis may be rendered somewhat less grave by remembering that pulsation has been noted in a myeloid tumor.

Cancerous ulceration is usually preceded by a known and evident tumor, probably epithelial; but in some cases the malignant deposit may have been entirely interstitial, and in others the patient is not seen until extensive ulceration has destroyed any tumor that might have existed. Such cases occur most usually about the bones of the face; and I have seen death produced where the lower jaw was implicated in a case of this kind, by the extension of the ulceration into the lingual artery. During life some difficulty may be experienced in distinguishing this cancerous affection from the rodent or phagedænic ulceration, spoken of at p. 140; but it is a matter of little practical importance, since amputation or complete excision would be recommended in either case, if the patient's general condition admitted of it. The bones of the face are peculiarly liable to extensive destruction in cancroid ulceration and in

Fig. 595.



Malignant ulceration of bone. (Museum of the Royal College of Surgeons, No. 640.)

---

[1] Edinb. Med. and Surg. Journal, April, 1860, p. 963.

lupus, but the chronic course of these affections sufficiently distinguishes them from cancer.

In the macerated bone, malignant ulceration produces extensive and irregular destruction both of the compact and cancellous tissue, without any trace of the periosteal and other inflammatory deposit that bounds the more healthy forms of ulceration (see fig. 595).

NON-MALIGNANT TUMORS.

Tumors of bone are like those of soft parts in all important respects. They are innocent or malignant; the former being, for the most part, composed of some of the same structures as form the bone itself, in a more or less perfect state of development (homologous tumors); while the malignant tumors are composed of other structures, to which the osseous tissue in a state of health presents no analogues (heterologous). The parts which compose a bone are fibrous membranes, cartilage, the proper osseous tissue or granular base, and bloodvessels; together with the spaces or cancelli filled with fat, which give the bone the requisite lightness. Now any of these elements over-developed or imperfectly imitated may give rise to a tumor. The overgrowth of the fibrous tissue gives rise to the true fibrous tumor; its imperfect imitation by morbid action produces the various forms of fibroid or fibro-plastic tumor; excessive or misplaced growth of cartilage results in enchondroma; of bone, in exostosis. Whether the vessels of bone are ever simply over-developed, without any other morbid product, so as to form the "osteo-aneurism" spoken of by numerous surgical pathologists, is a question which has been discussed above. From the over-distension of the cellular spaces of bones, some of their cystic tumors probably arise; others are formed by a peculiar arrangement of the connective-tissue in tumors belonging to different classes; and some of the growths, which are classified with cysts, are merely entozoa in the cancellous tissue. Lastly, analogous to the fat and medullary tissue which fills the cavities of the bones, we have a class of tumors, the myeloid, which, since their first description by Mr. Paget, have not ceased to attract much attention, on account of the interesting surgical and pathological questions connected with them.

Enchondroma. — Cartilaginous and bony tumors can hardly be treated of separately, for although the well-marked specimens of either class present little similarity at first sight, some of each are so intimately related, that the two could not without confusion be made the subjects of separate sections.

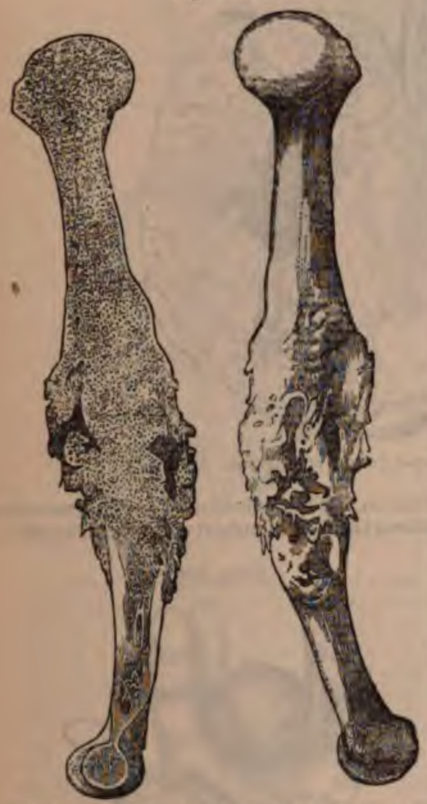
Cartilaginous tumors, or enchondromata, as they are called, have been already described in the essay on TUMORS (Vol. I., p. 261), so that it now only remains to speak of them as they affect the bones.

These formations may be divided, for surgical purposes, into two classes: the circumscribed and the diffused. [This distinction into diffused and circumscribed may, perhaps, lead to misconception, as the cartilaginous material is never diffused through the adjacent tissues in any such sense as are cancerous growths. It is true some of these tumors show a remarkable disposition to push their way in every direction, insinuating themselves into every space or opening to which they can gain access, and thus grow to a great size, perhaps in a region far from their point of origin. Some most interesting cases of this kind, for instance, are recorded, where this intrusive growth of the cartilaginous material has found its way inside of the spinal canal, and caused paralysis from pressure upon the cord. But in all these cases there is a distinct line of condensed areolar tissue limiting the growth, and separating it from the neighboring tissues which are displaced before it, but not infiltrated by it.

This form of cartilaginous tumor is, perhaps, the one that is most apt to assume a malignant behavior by local recurrence, and even, in rare cases, by generalization. In one case, which I saw several times with Dr. Gurdon Buck, he operated several times, at intervals sometimes of years, for recurrent growth, and finally the man died with immense masses of cartilaginous-looking material in some of the splanchnic cavities. No microscopic examination was made. In this case the tumor, growing first on one side of the nucha, involved more and more the deeper layers of muscles on the back of the neck, and, reaching down to the sides of the cervical spine, pushed some of its prolongations into the cavity, as was evidenced by slight but gradually-increasing paralysis. This course was taken by the growth in two recurrences, and in both, after as thorough an extirpation as could be accomplished, the paralysis disappeared.]

The former as a rule do, and the latter do not, show a tendency to ossify throughout their whole extent; although even in the diffused enchondromata the part of the bone from which they spring is often occupied by a considerable osseous deposit, while the bulk of the tumor remains unossified. The diffused enchondromata usually grow as extensive infiltrations into the tissue of the bone and periosteum, and in the course of time spread slowly over the surface of the bone (retaining for the most part their covering of periosteum), and fill all the spaces or cavities in relation with the bone. Such was the case in the instance shown in fig. 596, where the whole medullary canal of the shaft of the humerus is occupied for a considerable extent by porous bone forming the base of a cartilaginous tumor, which surrounded the bone, and had been growing for a long period without much inconvenience to the patient. It is difficult to determine their precise origin, and thus to make sure whether they are new formations, in a strict sense, or outgrowths; but the former opinion seems more generally probable. I have, however, met with one of these tumors, in the phalanx of the finger of a child, where it seemed probable that the origin of the tumor was the epiphyseal cartilage. [Of these tumors, springing from cartilage either epiphyseal or sutural, Virchow makes a class, calling them Ecchondroses. He claims that they present peculiarities in their history which entitle them to this separate consideration. In particular he notices the fact that they are sometimes found springing from the sutural cartilage which in young persons unites the occipital and sphenoid bone, and, projecting down into the cavity of the pharynx, form one variety of the growth which we denominate in general terms naso-pharyngeal polypus. It seems possible that the prognosis in these cases might not be so favorable as in the ordinary fibroma found in this region.] These non-ossifying cartilaginous tumors, or pure enchondromata, are little amenable to surgical treatment, unless in a part favorable for amputation. They have been supposed to present some analogy to malignant diseases, to which, indeed, their extensive diffusion and steady irresistible progress do offer a resemblance. They differ, however, from the true cancers at any rate in one feature, which is quite characteristic, viz., that however extensive their diffusion, they affect the surrounding parts only by pressure or absorption, not by contamination. This is their most distinctive feature; but it is not so useful in diagnosis (since it is less easily appreciated during life) as their rate of growth, which is usually slow. To this rule there are, however, rather frequent exceptions, of which three remarkable instances are related by Mr. Paget,[1] in one of which the rapid growth of the tumor led to the erroneous diagnosis of malignancy, and so deprived the patient of the chance of recovery which amputation would have given him. Remembering these and similar cases, we must not be too confident in inferring malignancy in the case of a tumor of bone from the single fact of rapidity of growth, although that is, doubtless, a most suspicious and unfavorable symptom. In many cases, these large cartilaginous tumors remain stationary for a long period; and this should be taken into consideration when consulting on the propriety of amputation.

Fig. 596.



The humerus in a case of diffused cartilaginous tumor (Museum of St. George's Hospital. Series ii., No. 183.)

The structure of these tumors varies; usually they are quite solid; in other cases cysts, filled with fluid, are found in them, as in the beautiful specimen from which the annexed figure (fig. 597) was taken. They sometimes consist exclusively of cartilage; but more commonly fibrous tissue is to be found, in sparing quantity, in some parts of them. The microscopical appearances will be found described in the essay above referred to (Vol. I., pp. 261, 318).

The circumscribed cartilaginous tumors are, however, much more frequently met with, and are, therefore, more important in practical surgery. They spring almost exclusively from the long bones, the pha-

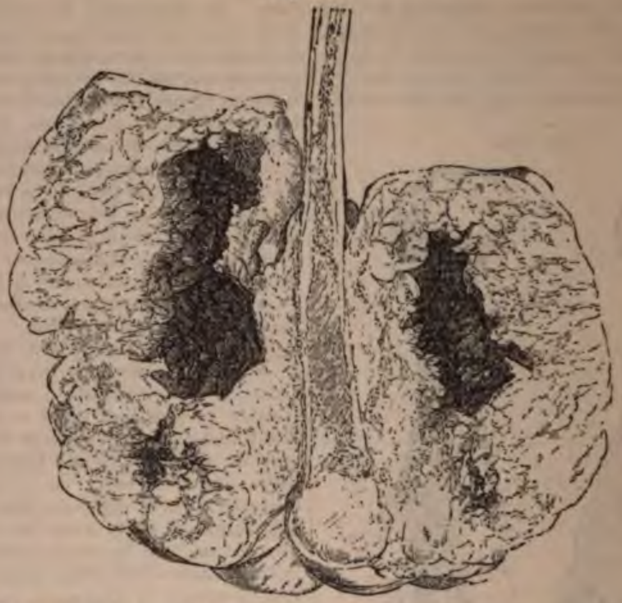
Fig. 597.

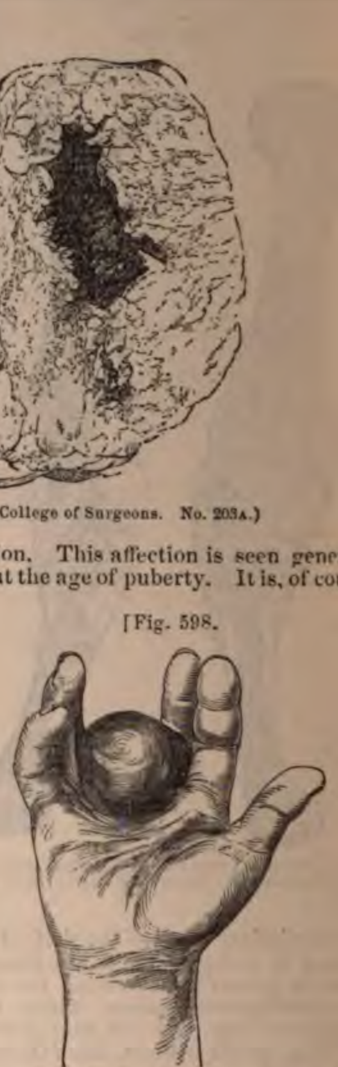


Cystic enchondroma. (Museum of the Royal College of Surgeons. No. 203A.)

langes of the fingers and toes being their most frequent seat. A small enchondroma is comparatively often met with, springing from the end of the last phalanx of the great toe, raising the nail up, and giving a good deal of pain in wearing the boot. It should be cut away from the bone, and usually will not return; should it do so the phalanx must be removed. [The removal of the entire phalanx seriously shortens the toe, and is not necessary. The growth is always from the upper surface of the phalanx and quite near its distal extremity, so that the removal of the anterior part of the bone, just at the sort of neck which supports the terminal enlargement of the phalanx, is entirely sufficient. In making this section of the bone, the entire nail will have to be removed by an incision which goes behind the matrix. If this is not carefully done small portions of the matrix may remain, which may give growth to irregular portions of nail, and become a source of great annoyance to the patient and vexation to the surgeon.]

In the hand and foot, enchondromata are often found in great numbers at the same time; and the appearance thus presented is very characteristic, and is not, as far as I know, imitated by tumors of any other kind. The fingers are studded over with bosses or knobs, looking something like the dry gnarled branches of an old tree. [Fig. 598 shows a solitary enchondroma of a metacarpal bone.] Of this form of disease fig. 599 is a good illustration. This affection is seen generally about the age of puberty. It is, of course, quite incurable, except by amputation; but that measure should never be resorted to in any disease of the hand without evident necessity. In the foot less scruple need be entertained, since the foot, deprived of its anterior portion, is still a very useful member, and there would be no necessity, even in a very advanced case, for going further than Lisfranc's or Chopart's operation. I have never seen a case where anything more was required

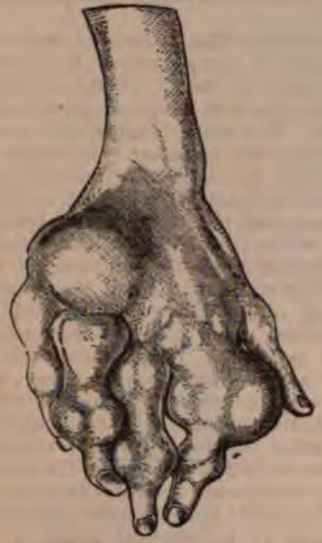
[Fig. 598.



Enchondroma of a metacarpal bone.]

than to remove one or two toes. In the hands, these multiple enchondromata, if left alone, grow generally very slowly, and sometimes not at all. Cases are, however, on record where they seem to have increased slowly during the whole period of life, and to have attained at length a truly extraordinary development. Of this the specimen figured by Müller[1] is an excellent instance; and a very similar case has been described and figured by the writer,[2] where, however, the cartilaginous structure was less distinct. Such tumors usually originate in the interior of a bone, expanding its walls into a thin bony cyst or shell, which is liable to give way at different parts, and firm pressure will then elicit a feeling of crepitation (see fig. 601, on p. 189). [Mr. Stanley states, that when a single tumor occurs on the finger or toe, it is usually found to grow from the outside, but when several fingers or toes are affected with these growths, they commonly originate within the bone.] These multiple enchondromata, like the diffused cartilaginous tumors just described, seem to show little tendency to ossify in the strict sense of the term; but they undergo, when very old, a process of calcareous degeneration, which, added to their general increase in size, produces ulceration of the skin over them; and so a condition is brought about not unlike that of a mass of enormous chalkstones exposed. More rarely the tumors spring from the surface of the bones.[1] [In contrast to this ossific change, a softening is occasionally observed in which the tumor loses its firm, elastic, characteristic consistence, and becomes converted into a soft jelly-like material, which at points becomes almost fluid. This is chiefly seen in old and very large tumors, and doubtless may be regarded as a degeneration.]

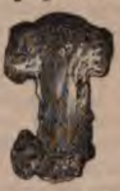
Fig. 599.



Model of a hand affected with numerous enchondromata. (From the Museum of St. George's Hospital.)

Circumscribed and solitary enchondromata usually grow from the surface of a bone, and most of them show a strong tendency to ossify, the process commencing generally at the base. Hence the surgical considerations applicable to them are identical with those which apply to exostosis. When a circumscribed enchondroma grows in the interior of a bone, as in the figure above referred to, it can be readily enucleated, and when a small cartilaginous tumor springs (as it often does) from the end of the last phalanx, usually of the great toe, its removal is very easy, and is always, as far as I

[Fig. 600.



Sub-ungueal exostosis of phalanx of great toe.]

[1] Ueber den feinern Bau und die Formen der krankhaften Geschwülste. Berlin, 1838, tab. iv., fig. 1.

[2] Path. Soc. Trans., vol. ix., p. 382. The specimen is in the Museum of St. George's Hospital.

[1] With regard to the ordinary seat of cartilaginous tumors of bone, Dr. Pirrie makes the following observations, which I believe to be generally true: "I have now seen in my own experience nine specimens of cartilaginous tumors near the ends of long bones, and they have all been situated between the walls of the bone and the periosteum, and in no instance extended to the cartilage of incrustation at the end of the bone. I have met with fifteen examples in metacarpal bones, and they all originated within the bone, and caused more or less of expansion of the walls and their conversion into a thin crust or shell around the tumor, in various instances at parts completely absorbed. I have seen and carefully examined seven examples of the same kind of growth in the middle of the long bones, and they were all placed within the canal and around the wall of the bone. Judging from my own comparatively limited experience, I would conclude that the favorite site of the first class is around the bone; of the second within it; and of the third, both within and around it."—On Acupressure, p. 107.

have seen, permanently successful. [Fig. 600 shows one of these sub-ungueal exostoses, the surface only of which was cartilaginous, which grew from the side of the end of the last phalanx of the great toe.]

Diagnosis.—The diagnosis of innocent tumors from each other is uncertain and obscure in all parts of the body, and perhaps more so when they are connected with the bones, on account of the generally deep position of the latter. If, however, a tumor presenting the general characters of innocency can be clearly made out to be springing from bone, the chances are very great in favor of its being an enchondroma or an exostosis. If very large, it can hardly be the latter without displaying characteristic hardness. Fibrous and fibroid tumors may be found of large size; still almost all large non-malignant tumors of bone are cartilaginous. Most, also, of the smaller tumors, which do not possess the hardness of exostosis, will be found to be cartilaginous. Such tumors usually possess a certain amount of resilience, and often appear obscurely movable on the bone. This sensation, however, is often deceptive, and due, apparently, to the motion of the soft parts upon the tumor; it has been noticed in tumors, the base of which has been found to be completely ossified, and a slight amount of apparent movement is therefore no conclusive reason for denying the connection of a tumor with the bone. Another thing which ought to be taken into account in diagnosis is, that the cartilaginous, equally with the osseous, tumors may have a bursa over them. This will not often be an obstacle in the way of making out an exostosis, since the hardness of the latter is transmitted through the fluid, but may sometimes cause a doubt about the nature of an enchondroma. The nodulated surface of enchondroma, though characteristic to a certain extent, is far from distinctive of the disease; the same property may belong to colloid disease, fibrous tumor, and other swellings; in fact, the only sensation which affords a reasonable ground for pronouncing a tumor cartilaginous is resilience combined with solidity; and this for deep-seated tumors is often deceptive, and in the many enchondromata enclosed in shells of bone is, of course, absent. On the whole, therefore, an enchondroma is best known by its being an innocent, and not osseous, tumor; elastic when firmly pressed, generally growing slowly, and not affecting the skin. When the phalanges are the seat of the disease, the diagnosis is much more nearly certain. [While the innocence of the cartilaginous tumor is conceded by all, yet the fact must not be overlooked that pure cartilaginous growths have been known to recur after removal, to extend to neighboring regions, and even to become generalized, still preserving both in the recurring and in the metastatic growths their perfect histological composition.]

Exostosis.—The transition from cartilaginous to bony tumors is a natural one, since so many of the former are merely the first stage of growth of the latter. The term "exostosis" is not a very easy one to define. It ought to be used only to signify an innocent tumor, or limited outgrowth, formed exclusively of bone, and not the result of inflammatory action; but, on the one hand, the products of inflammation secreted by the periosteum often assume the form of a limited outgrowth or tumor; while, on the other, many complex malignant tumors possess a bony framework, and, after maceration, bear a great resemblance to exostosis. In the latter case the distinction, though occasionally difficult after the bone has been macerated, is easy during life; so that the mere fact that a malignant tumor possesses a more or less perfect bony framework is of little moment in a practical point of view. Most of the growths which fall under the category of "periosteal exostosis"[1] are extensive inflammatory deposits beneath the periosteum, which neither require nor admit of surgical treatment. Whether limited, pedunculated, and therefore removable, tumors ever occur as a consequence of inflammation is as yet doubtful; but it is highly probable that they do, both from the analogy of the elongated processes sometimes found projecting from the bone in the neighborhood of fractures which have been consolidated with more than the usual amount of inflammation,[2] and also from the following considerations: Exostoses are occasionally found attached to the bone only by a neck composed of fibrous tissue. The occurrence of masses of new bone around the articular ends in the inflammatory disease known as "chronic rheumatic arthritis," and the probability that such masses become subsequently blended with the original bone, is now a familiar fact in pathology.[3] Specimens have been exhibited in which it seemed that inflammatory appearances could be traced around some of the loose exostoses previously referred to;[1] so that it is possible that some exostoses may be developed, as the masses of bone are which form so striking a feature of chronic rheumatic arthritis, in the soft structures near the bone, as a result of inflammation, and may afterwards coalesce with the original bone. The great majority, however, of those bony tumors which are called, in surgical language, exostoses, originate by an outgrowth or limited hypertrophy of analogous parts, just as fatty, fibrous, and other innocent tumors do, quite independent of any inflammatory symptoms. Many authors, especially the French surgeons, speak of "bullous exostoses," meaning apparently by this term those shells of bone which sometimes are formed by the development of a tumor (generally cartilaginous) in the centre of the shaft. Such a case was the one from which the accompanying figure is taken. Another kind of exostosis is that which proceeds from the ossification of tendons, or from the occurrence in man of processes of bone natural to the lower animals. Both of these belong rather to the class of museum curiosities than of subjects of practical interest. Still, if they became objects of treatment, they would probably be indistinguishable from exostoses, and would require the same operation. Few museums are without a specimen of ossification of tendons and other fibrous tissues. Some cases of this kind will be found referred to in the essay on AFFECTIONS OF THE MUSCLES, where also the treatment of persons presenting this tendency is discussed. Such cases as those in which a process projects from the humerus around the brachial artery, when that vessel follows the course usual in the large feline animals, in which it is surrounded by a ring of bone, only need to be known in order to avoid operative interference; and in any operations on bony tumors in regions where such anomalies are known to exist, the nature and history of the case ought to be first carefully investigated.

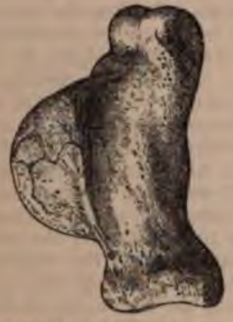
[3] On this head I would especially refer to a paper by Mr. W. Adams, in Path. Soc. Trans., vol. iii., p. 156.

Fig. 601.

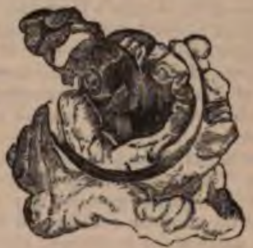


Bullous exostosis on the phalanx of a finger; probably a shell of bone expanded around a cartilaginous tumor. (From a preparation in St. George's Hospital, Series ii., No. 151.)

Excluding these rarer varieties, the cases of circumscribed exostosis which surgeons have to treat are divided into two classes—the cancellous, and the ivory; the former being a reproduction of the tissue of the interior, as the latter is of the hard exterior of the bone. They will be found fully described in the essay on TUMORS (Vol. I., p. 265).

Treatment.—The slow rate at which exostoses progress, and the ease with which the soft parts accommodate themselves to the gradual advance of the tumor, render it frequently unnecessary to meddle with them; and it is always right to defer the operation until it is clearly seen to be necessary; since there is always great risk in operating on any deep-seated tumor, and still greater in laying open the cancelli of bone, as must be done in dividing the neck of an exostosis. Diffuse suppuration in the intermuscular spaces, erysipelas, and pyæmia are very liable to follow such operations. When the exostosis is of the ivory variety, and situated on the cranium, the operation is much more dangerous. Here, indeed, it not unfrequently happens that the tumor is so hard as to resist all the tools which can be brought to bear upon it, so that it is physically impossible to remove it.

Fig. 602.



Ivory exostosis which was trephined unsuccessfully, on account of its great hardness. Exfoliation was afterwards produced by the long-continued application of caustics—chiefly nitric acid. (From the Museum of St. George's Hospital, Series ii., No. 189.)

[The ivory exostosis is sometimes circumscribed, forming a mass, set, as it were, in the midst of bone-tissue otherwise sound, and therefore offering a chance for removal. These cases are most common in the bones of the face, and many successful operations are recorded. Their favorite seat seems to be the neighborhood of the orbit.

A singular fact in the history of such growths is that they are sometimes found detached and lying loose in the cavities of the face and skull bones. Dr. Duka, London Path. Soc. Transactions, vol. xvii., reports a case in which an ivory mass was found loose in the nasal cavity, where it was known to have existed for six years. It was removed by operation, and it is stated that "the whole bony mass weighs one thousand and sixty grains; its long diameter is nearly three inches, the short one an inch and two lines, and the longest circumference seven inches." Mr. Hilton, in Guy's Hosp. Rep., vol. i., gives an instance of a similar tumor, much larger in size, which had existed for twenty-three years, and which, on operation, "fell out of a large cavity in the superior maxillary bone."

---

[1] Gay, in Path. Soc. Trans., vol. iv., p. 244.

On the other hand, this form of ivory-like growth is sometimes diffused over considerable portions of bone, seeming more like a localized hypertrophy than a tumor. These growths are characterized by steady, though sometimes very slow, extension, which proceeds in all directions, encroaching upon the cavities of the nose, the orbit, the mouth, the pharynx, and finally, by pressure on the brain, terminating the existence of the long-suffering patient.]

A striking example of this occurred in a case which has furnished a preparation to the Museum of St. George's Hospital. A man, suffering from a small ivory exostosis in the frontal region, fell under the care of the late Mr. Keate, one of the boldest and most skilful operators of his day, who perseveringly, but vainly, endeavored, by the use of trephine, saw, chisel, and mallet, during the space of nearly two hours, to cut off the little lump of hard bone. The patient was fortunate enough to recover from this proceeding; and Mr. Keate, convinced of the uselessness of further operation, determined to attempt the extirpation of the tumor by the free application of potassa fusa and nitric acid to its exposed base. This was successful. The caustics, in the course of years, ate their way through the base of the tumor, which dropped off. The tumor figured in the accompanying illustration (Fig. 602, p. 189) still shows the deep groove worked into it by the trephine at the time of the operation.

It would be rash to say that such operations are unjustifiable, since exostosis in the neighborhood of the orbit may grow into that cavity, or into the cranium, and cause death, or some horrible deformity almost worse than death, by displacement of the eyes, or bones of the face;[1] but the risks of operating on these small exostoses about the cranium should be maturely weighed. Some tumors, however, which present on the surface the character of the true ivory exostosis, may turn out on section to be hard only on the exterior, and to consist of a soft diploic tissue internally. This is the case usually, if not solely, when the bone from which the tumor springs resembles the composition of the vault of the skull, that is to say, consists of diploë covered by a thin table of compact tissue. In bones of which the shell is more dense, such as the lower jaw, it is much more probable that the whole thickness of the tumor will be of compact structure. The exostoses which consist of diploë internally covered by a thin shell of hard substance (and which I venture to think more common than they are usually said to be), are, of course, much more easily removed than the true ivory exostoses which they simulate; and another circumstance which renders the prospect of operations on large exostoses, whether on the skull or other parts, rather more promising than would appear at first sight, is that the tumor when exposed is sometimes found to be connected to the surface of the bone by a very narrow neck, from which it can be easily broken or cut off.[1] [This neck is composed, as is the tumor, of an external compact wall and internal cancellous tissue, a communication taking place through the neck between the cancelli of the tumor and those of the original bone.

Mr. Stanley asserts that this neck does not grow with the tumor, or, at least, not at the same rate. It has been proposed to divide the neck subcutaneously, with the view of checking the further growth of the exostosis. This was suggested by cases of accidental fracture through the neck, which it was found arrested the growth, and occasionally caused shrinking of the bony mass. No very marked result has been reported, and in one case in which Mr. Maunder performed the operation, adhesion of the divided bony surfaces took place, though it is stated that the union left the growth in a better position than it occupied before the operation.

These growths give rise to no symptoms except such as arise from pressure of the encroaching mass on surrounding tissues. These pressure-effects are the usual reasons for operation, and often fully justify it. Some very remarkable instances are cited. Mr. Stanley speaks of an exostosis growing from the posterior surface of the clavicle, which pressed upon the axillary plexus of nerves, and gave rise to very severe suffering on every motion of the limb. In another case an exostosis, springing from the first rib, seriously compressed the subclavian artery. Other cases are recorded where the œsophagus, the bladder, the brain, and the spinal cord have suffered compression from this cause.]

---

[1] Some remarkable specimens are in the Museums of St. Bartholomew's Hospital and of the College of Surgeons. Exostoses of the orbit are not always of this dense quality. See a case in Path. Soc. Trans., vol. xi., p. 264, where the tumor was soft, and easily removed.

[1] A most interesting case of a tumor of this kind, growing from the cranium, is reported in the Path. Soc. Trans. for 1850, p. 149, with a drawing, and has been commented on by Mr. Prescott Hewett in his Lectures on Diseases of the Head.

It is, however, only rarely that either the surgeon, or the patient, will make up his mind to the dangerous and doubtful experiment of an operation on an ivory exostosis, especially of the cranium; whereas operations on the more common forms of exostoses which spring from the shafts of the long bones, and present the cancellous, or mixed cartilaginous structure, are of daily occurrence. Their most common situation, after the phalanges, is near the knee, springing from the inner surface of the femur, a little above the condyle. Another very common situation is beneath the deltoid muscle.

The removal of such an exostosis is, in most cases, easy, since the base is not generally very broad, nor the ossification very compact. Some are even so soft as to be divisible with a strong scalpel. A few again are not united to the shaft by bony matter, but by ligamentous union.[1] This condition is highly favorable for operation, not merely because the tumor can be more easily excised, but also because the vascular spaces of the bone will not be laid open in the operation.

In other cases the tumor is broader and more firmly ossified at its base than in any other part; and these are the least favorable cases for operation, since the division of so large a mass of bone requires great and prolonged violence, peculiarly likely to be followed by the complications above enumerated. But the operation is necessary when the tumor is growing, and is threatening the functions of important parts; and in such cases the operator must be prepared for the difficulties which he may have to encounter, and should have a sufficient supply of instruments of adequate strength at hand, such as stout bone-nippers, a chain-saw, other saws of various shapes, chisels, and mallet. In all cases the base of the tumor should be clearly exposed, and separated with care from the parts around, which may require to be held back with retractors. The separation should be commenced from the side where any danger is to be apprehended (*e. g.*, in consequence of the proximity of a vessel or joint), in order to avoid implicating any important part; and then any amount of force necessary must be carefully but firmly applied, the bone being steadied by assistants.[1]

The "bullous exostosis," or central enchondroma contained in a bony cyst, usually requires amputation of the phalanx upon which it is seated.[2] It may, indeed, be sometimes possible to enucleate the growth, and I have seen this done with success; but as a general rule it is hardly worth while to attempt it; since, if the disease be seated in the hand, the necessary disturbance of the tendons would probably render the finger useless; and if in the foot, the certainty of a speedy and complete recovery would outweigh the advantage of preserving a portion of one of the toes.

Diffused bony, or innocent osteoid tumor.—Besides these forms of limited exostoses, a diffused bony tumor is occasionally met with, in which the whole thickness of the bone for some distance is converted into a lobulated mass of spongy bone, which, in a section of such a tumor that I had the opportunity of examining microscopically, presented the usual structure of bone, but with smaller cavities, and an increased deposit of the granular base.

The specimen (in the Museum of St. George's Hospital, series ii., No. 185) is larger than a man's fist, and involves one side of the lower jaw, from the condyle to near the symphysis. Its innocent nature is clearly proved by the fact that it had been growing for five years without any detriment to the general health, and had been partially removed on a previous occasion without any ill consequences from cutting into the interior of the tumor. On the patient coming under the care of Mr. Tatum, the tumor was completely excised, and with success, as the man was seen in perfect health several years afterwards.[1]

---

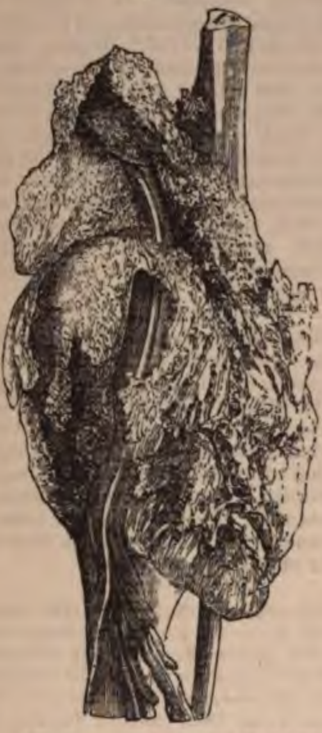
[1] The observations made on pp. 188, 189, and the case of Mr. Gay's patient there referred to, will render it probable that exostoses are sometimes formed in the soft parts around the bone. These, of course, are connected to the bone, at least originally, by ligamentous tissue. Again, ossification of an enchondroma may proceed from without inwards, instead of its more usual course from within outwards. In a third class of cases, exostoses may be movable on the bone as the result of fracture. See a preparation in the Museum of St. Bartholomew's Hospital, series A, No. 183.

[1] It may not, perhaps, be out of place to remark, that in case of an exostosis situated near the knee-joint, there is the more danger of opening the joint, since the presence of the tumor has probably caused numerous attacks of synovitis, which have left the pouch of synovial membrane extending up the thigh permanently enlarged.

[2] I have never seen a tumor of this sort connected with the larger bones; but the statement in the text would apply still more forcibly to such a tumor.

Another still more remarkable case is illustrated by a series of three preparations in the Museum of the College of Surgeons. The history is so interesting that a condensed report of it must be introduced. The thigh was originally amputated on account of a hard and heavy dry osseous substance, surrounding the ends of the femur and tibia, projecting into the knee-joint, extending far up the thigh, and implicating the popliteal artery, vein, and nerve, so as to cause œdema and severe pain (Prep. No. 3244) shown in the accompanying figure. The patient remained well for five years; then another osteoid tumor formed on the stump of the femur, accompanied with severe pain. Amputation was performed higher up. The tumor appeared to grow, not from the bone itself so much as from the periosteum, and enclosed the femoral artery (Prep. No. 3245). There was again an interval of health for two years; then a fresh tumor formed about the stump, continued to increase upwards, out of reach of operation, and finally killed him, from inflammation and sloughing of its soft coverings, *twenty-five years* after the first appearance of the disease. He had been in good general health during the whole time (Prep. No. 3245, A).[1]

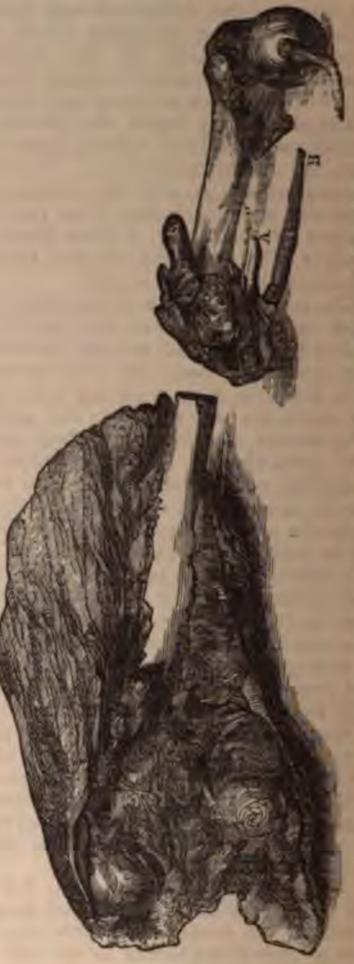
Fig. 603.



Diffused bony tumor of the femur and tibia: the popliteal vessels and nerve are seen surrounded by the bony growth, the veins varicose from the pressure. The tumor overlaps the fibula, which, however, is not affected. (Museum of the Royal College of Surgeons. No. 3244.)

[Fig. 604 shows the femur, as it appears in Dr. W. H. Van Buren's collection, taken from a man with an almost precisely similar history, with the exception that in Dr. Van Buren's case, the disease recurred in the pelvic bones, which were enormously enlarged by a deposit similar to those represented in the cut. All these tumors had an osseous or osteoid character, and were covered mostly by a thin layer of cartilage. This was the view at the time,

Fig. 604



Femur from a case of Dr. Van Buren's; probably a periosteal osteoid sarcoma.

---

[1] Path. Soc. Trans., 1848–9, p. 95.

[1] Another, and very similar, case may be found in Mr. Paget's Lectures on Surgical Pathology, vol. ii., p. 506.

but it seems probable that the disease was really an osteoid periosteal sarcoma.]

This history presents a remarkable analogy to that of the recurrent fibroid, or fibro-plastic, tumors of soft parts. There are the same leading features, viz., the local malignity of the disease combined with innocence constitutionally, its imperfect imitation of the tissues in which it grows, its constant recurrence near the site of an operation, and, finally, the mode of death—from exhaustion and sloughing after repeated operations, not from infection of the system.

Cysts in bone are of two kinds; viz., serous and sanguineous. The serous, or mucous, cysts which occur in the jaws as a consequence of irregularity of the growth, or position, of the teeth have been treated of in a former essay. [See Vol. II., p. 571.] In such cases the formation of a cyst containing clear fluid is susceptible of an intelligible explanation; but it is difficult to see how simple serous cysts can be developed in other bones, and probably the few cases which are to be found in books rest upon erroneous diagnosis.[1] But cavities containing clear fluid are formed in bones by the growth of hydatids in their interior; and if simple cysts do occur, they would be indistinguishable from hydatid cysts before operation, and would require the same treatment.

Blood-cysts are not of common occurrence, nor is it usually easy to determine their pathological nature. Many of the cases reported under this title appear to have been examples of malignant tumor, in which a cyst has been developed, much exceeding in relative size the solid portion of the growth.[2]

The most distinct description of a blood-cyst in bone to which I can refer is by Travers, in the Med.-Chir. Trans., vol. xxi. He excised the greater part of the clavicle, on account of a large cystic tumor of about a year's growth, which was very clearly connected with a history of injury. The tumor consisted of an arrangement of cells or chambers, of pretty equal dimensions, filled with dark solid coagula of blood, with spicula of bone in their walls, and invested by a very stout fibrous membrane. "The investing membrane was evidently the condensed periosteum, the cells were the irregularly-expanded cancelli, and the calcareous particles were the débris of the bony plates and walls." Travers is inclined to attribute the disease to expansion of the bony cancelli from blood effused into them as the result of violence. If this explanation be accepted, the affection would be identical with the blood-tumor, or hæmatoma, which is occasionally found in the soft parts as the result of contusion (see Vol. I., p. 385). Mr. Stanley also relates a case[1] in which he amputated the thigh successfully on account of a blood-cyst originating in the condyles of the femur, and where both the femur and the tibia presented "an ecchymosed condition from minute effusions of blood through their compact tissue." This condition existed in the femur up to, if not above, the level of the amputation; yet the disease had not recurred six years afterwards. Mr. Stanley, however, in his description of this tumor, is careful to mention the fact that there were distinct portions of solid matter attached to the inside of the cyst, and would evidently, but for the progress of the case, have been inclined to refer it to the incipient stage of cancer.[2]

Blood-cysts could only be distinguished from serous or hydatid cysts by puncture. In the great majority of cases they would require complete removal, by amputation if necessary. If the surgeon can satisfy himself of the absence of all soft solid matter around the cyst, he may in rare cases be justified in endeavoring to procure its obliteration by laying it open and stuffing it with lint; but it must be borne in mind that such measures can only do harm if there be anything of a malignant taint about the disease.[3]

Fibrous and fibro-cystic tumors.—The great majority of the innocent tumors of bone which are not osseous will be found to be cartilaginous or myeloid; but a smaller number present the fibrous character more or less perfect. Perfect fibrous tumors appear as outgrowths from the periosteum; and the most familiar examples of them are the fibrous polypus of the nose, which is treated of in the essay on DISEASES OF THE NOSE, and epulis, which will be found treated of among the DISEASES CONNECTED WITH THE TEETH. As in other situations, a fibrous tumor could hardly be distinguished from enchondroma before removal, and the diagnosis, even if it could be made, would be quite unimportant. We need not, therefore, give examples of the disease occurring in other parts of the body. Scattered specimens will be found in most of our large museums, and in many of them ossification will be found to have made some progress. In some of these cases the innocent nature of the disease is proved by the history, in others it is an inference from the structure of the tumor. Calcification occurs in these as in other fibrous tumors (St. George's Hospital Museum, ser. ii., No. 152).

---

[1] Mr. Stanley (op. cit., p. 194) denies the formation of simple cysts in any other bones than those of the jaw.

[2] See a case reported by Mr. Liston, under the name of "ossified aneurism of the subscapular artery," Ed. Med. and Surg. Journ., vol. xvi., pp. 66, 215.

[1] Op. cit., p. 187.

[2] It is possible that this affection may have been, as Mr. Paget hints, a myeloid tumor, in which the cysts, which are so common in that disease, were developed out of proportion to the solid part (see vol. i., p. 265).

[3] In Nélaton's Path. Chir., vol. ii., p. 48, will be found a striking representation of a large multilocular cystic tumor developed in the femur, and containing bloody fluid. Unfortunately there is no history of this case.

Fibro-cystic tumor of bone is a disease which is little known, and may therefore possibly be of very rare occurrence. It is, however, also possible that this apparent rarity may be due to the fact that most of the examples of this disease have been confounded with malignant tumors. A very interesting account of a growth of this sort connected with the femur, in which the limb was removed at the hip-joint by Mr. J. Adams, will be found in Path. Soc. Trans., vol. v., p. 254, and, appended to the account of this case, a report by Mr. Prescott Hewett on three similar cases, in all of which the femur was the seat of the disease, and in all of which the patient recovered after amputation, and remained well for many years afterwards. There is therefore the strongest reason to believe that the disease was not cancerous. It commenced, in each of the four instances alluded to, in the cancellous tissue of the bone, making its way outwards, infiltrating the shaft, and causing spontaneous fracture; so far, therefore, exactly resembling cancer. It gave the sensation of an elastic substance, with fluid here and there in cavities. There seems to have been no diagnostic mark between it and cancer during life, except the negative indications to be derived from the absence of glandular or constitutional contamination during a somewhat long disease, the duration of the affection being, in the two cases in which that point was noted, three and four years respectively. On examination after removal, the innocent nature of the disease was inferred from the large quantity of firm, glistening fibrous tissue of which nearly the whole solid portion of the tumor was formed, the presence only of such cellular elements as are found in growing fibrous structures, and the absence of cancer-juice, or any other indication of a tendency to disintegration in the tumor, or infiltration of neighboring tissues.

Myeloid tumors, the only other form of innocent tumor which it is necessary to particularize, will be found sufficiently described in Vol. I., p. 264.

Entozoa in bone.—A very few words must suffice for the description of the cases of entozoa in the interior of bone. The entozoon appears to have been the ordinary echinococcus in all cases except one quoted by Mr. Stanley, in which the cysticercus telæ cellulosæ is said to have been found in the interior of one of the phalanges. The subject is of no very great practical importance, since it is seldom possible to diagnose the nature of the affection previous to operation. The cases are so rare, that in the great work of Rokitansky[1] only eight are referred to, as the total number which he supposes to have been then observed. A search, however, through the various pathological collections would probably discover many more than these.[2] It is noticed by Rokitansky,[3] that the disease appears often to be directly induced by some injury; but it is difficult to believe that this can be otherwise than accidental. The disease runs a protracted course, and if the shaft of a long bone be the part affected, fracture, spontaneous or accidental, is very probably the first thing noticed. The fracture, in all probability, does not unite; and it has sometimes happened that in an operation, undertaken for the purpose of resecting the ends of the fracture, the hydatid cavity has been exposed and the globular acephalocysts discharged.[4] Amputation is then indicated in ordinary cases; but one is on record, in which the hydatids were scooped out of the cavity of the cyst, which then filled up, and a complete cure was obtained.[5] In other cases, the seat of the disease is in a flat bone, as the skull,[6] or ilium,[7] or in the expanded head of one or more of the long bones.[8] These cases are quite within the reach of cure when their nature is discovered; and in some rare instances, as in Mr. Coulson's and Mr. Stanley's cases, the discharge of hydatids through a spontaneous opening or a puncture, enables the surgeon to determine the nature of the disease beforehand. Failing this, the symptoms are precisely those of any other cystic tumor of the bone.

[6] Keate, in Med.-Chir. Trans., vol. x., St. Thomas's Hosp. Museum, c. 6^{1}.

[7] Stanley, op. cit., p. 190.

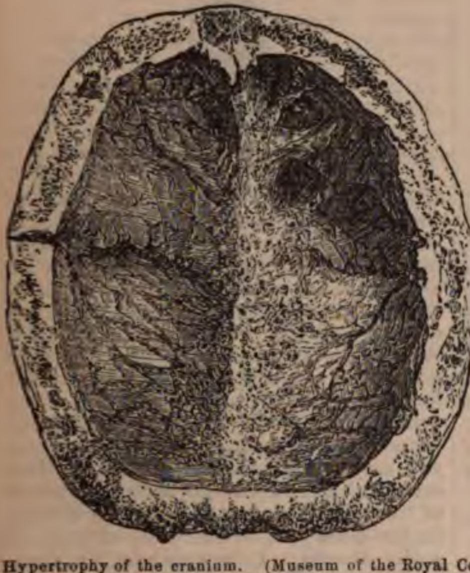
[8] Coulson, in Med.-Chir. Trans., vol. xli. In the specimens in St. Thomas's Hospital Museum, c. 253-4, hydatids were found simultaneously in the lower end of the femur and contiguous head of the tibia. Other cases are noticed in the bodies of the vertebræ. Dupuytren, loc. cit. Guy's Hospital Museum, No. 1029^{30}.

The treatment appears to be usually successful. The cyst is to be freely laid open, with the trephine or bone-nippers if necessary; and all the hydatids removed, and some caustic[1] applied to the whole interior of the cyst. In most of the recorded cases this has been sufficient; but in Mr. Coulson's case the cure was not completed until after the separation of a small piece of bone from the floor of the cavity, which on examination was found thickly studded on both surfaces with a great number of minute hydatids.

HYPERTROPHY AND ATROPHY OF BONE.

The condition of bone usually known by the name of hypertrophy is very generally the consequence of chronic osteitis, and would perhaps be more conveniently designated by some name expressive of its inflammatory origin. Thus, most of the specimens of "hypertrophied cranium" seen in our museums will be found, if the history be known, to be taken from cases of injury, or to be connected with syphilis or scrofula. The cases also of elongation and thickening of the bones of the leg, related by Mr. Stanley[1] under the head of "hypertrophy," appear all of them to fall more naturally under consideration with the sequelæ of inflammation, which have been described above. It appears that this thickening may go on for an indefinite period after the cessation of any symptoms, and that the enlargement of bulk which follows from it is permanent.

Fig. 605.



Hypertrophy of the cranium. (Museum of the Royal College of Surgeons. No. 2858.)

[True hypertrophy, however, does occasionally occur in bone when the actions seem to be those of simple adaptation to changed conditions, as is seen in the heart, when, from valvular disease, increased labor is thrown upon its muscular fibres; those fibres become increased, not merely in size, but in power. They have more work to do, and they gain more power to do it. So in the case from which fig. 606 was taken (see p. 196). It was from a young man who had necrosis of the tibia, with little or no involucrum to supply the loss of bone which had died and been removed by operation. He was, however, able to get about, bearing some weight on the limb, for about eighteen months before his death. It is shown in the specimen, which we have in the Museum of the College of Physicians and Surgeons, that no weight could have been received on the tibia, for a little new bone which has been thrown out is not continuous along the shaft, a small space being ligamentous. The whole weight, therefore, must have been borne by the fibula, which the figure shows has acquired three times the thickness, and probably more than three times the strength, of its fellow of the opposite side.]

It is true that in many of the cases of thickening, whether of the skull or of the long bones, which are preserved in pathological collections, no history of injury or inflammatory affection has been obtained; but the exact resemblance of the specimens to those in which such a history does exist, leaves no doubt that most of them are specimens of chronic inflammation. Cases do, however, occur, though so rarely as to be rather matters of curiosity than of practical interest, in which a bone (the skull for the most part) has gone on increasing in size without any symptoms except those produced by its increase in bulk. Such was the well-known instance related by Mr. Prescott Hewett, in his lectures at the Royal College of Surgeons, in which a man's skull continued to increase in size from year to year, with no symptoms whatever, so that he was only aware of the fact from

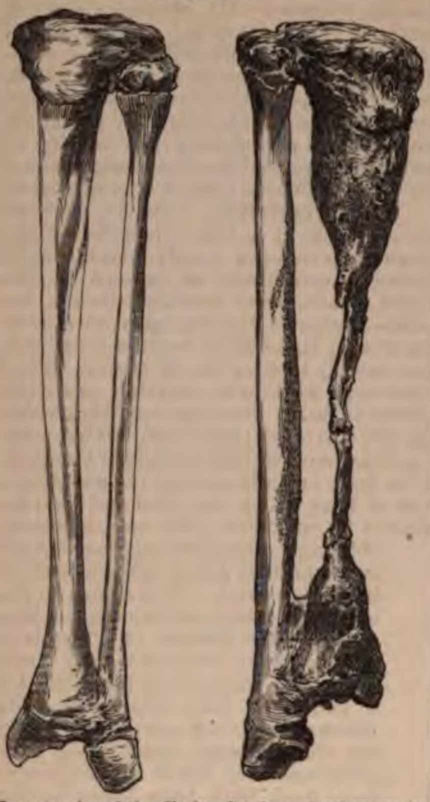
[Fig. 606.

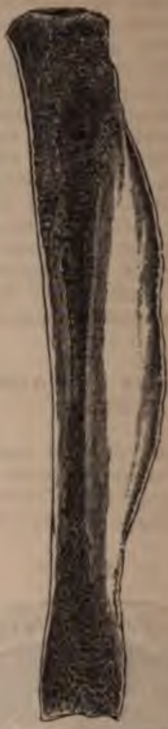


Hypertrophy of the fibula after loss of substance in the tibia by necrosis.]

the increasing size of his hat. The disease, however, in this case was clearly traced to an injury. As no symptoms can be attached to such cases, no treatment is known to have any influence upon them. In the absence of any constitutional affection, the persevering use of counter-irritation, by iodine or blistering, would appear to hold out most hopes of checking the growth. [Fig. 607 shows the condition of hypertrophy with condensation of tissue, often called eburnation.]

Atrophy of bone is a more frequent and a more important disease than the opposite condition of hypertrophy. Inflammation, fatty degeneration, disuse, and injury are frequent causes of atrophy; and there is also a simple atrophy, in which the composition of the bone is unaltered and in which no obvious cause is present (unless it may be the general failure of nutrition in advanced life), and where the amount of bony tissue becomes gradually less and less, until the bone is no longer strong enough to resist slight violence.[1] As a consequence of senile change, or fatty degeneration, atrophy is one of the most common causes of spontaneous fracture. It may also occur in any bone, to some extent, as a consequence of confinement during a lingering disease.[2] Brodie says,[3] "All bones in a state of inaction lose a great part of their phosphate of lime. After compound fracture, when the patient has been long confined, the bones in some instances become as soft as a scrofulous bone, so that you may cut them with a knife." The cases which are spoken of under the name of "fragilitas ossium" appear to belong for the most part to the class of fatty or senile atrophy. Injury sustained in fracture is also a frequent cause of atrophy. Of this, the most extraordinary instance is that quoted by Norris,[4] in which, after two fractures occurring at the same point, near the middle of the humerus, the

[Fig. 607.



Hypertrophy with condensation (eburnation).]

[3] Lect. on Pathology, p. 409.

[4] Amer. Journ. of Med. Sci., Jan., 1842, p. 39.

whole bone disappeared, so as to leave the forearm "swinging hither and thither like a thong," and the arm shortened six inches. It is expressly stated, in the account of this curious case, that there was no open sore, and that the bone disappeared "by the gradual action of the absorbents." Mr. Curling[1] believes that the cause of atrophy after the fracture may often, if not always, be found in injury to the medullary artery. Even allowing, however, that this explanation is plausible in some cases, there are others (not to speak of extreme instances like the one just cited) where it cannot apply. Such are cases of atrophy of both fragments, or of the bone in the neighborhood of the fragments, while the latter are not so much atrophied.[2] Atrophy from inflammation is a condition illustrated by many morbid preparations, though it does not attract much attention in practice. It is merely the persistence of that degenerative change which leads to inflammatory softening; and probably many of the cases of atrophy after fracture should be referred to this head.

Connected with atrophy is the suspension of growth, occasionally, though rarely met with, in which the epiphyses remain separate from the shaft of the bone; and it seems probable that injury to the epiphyseal cartilage, in separations of the epiphysis, may occasionally give rise to shortening of the bone from suspension of growth between the shaft and epiphysis.[3]

Atrophy of bone is an affection which does not appear to be marked by any peculiar symptoms, or to admit of any special treatment. After injury to any part, the restoration of moderate functional activity as soon as it can prudently be recommended, the avoidance of any cause of pressure on the main vessels or those of the surface, and the choice of a suitable posture, with attention to the general health and nutrition, are the objects of a judicious treatment, irrespective of the condition of any particular part; and these measures are all that could be suggested to avert atrophy of the bone, even if it were known to be impending.

Spontaneous fracture has been mentioned repeatedly in the previous pages, in connection with several morbid states, which may be thus enumerated in the order of their presumed frequency as causes of fracture: viz., senile atrophy, malignant disease, tumors of other kinds, including hydatids; the ulceration which accompanies necrosis, and, lastly, other kinds of ulceration. But besides these, cases of spontaneous fracture occur without known cause; sometimes in making a violent muscular effort, as in throwing a stone, or striking a blow; at other times in the most ordinary action, as in turning in bed, quiet walking, etc. Those which are caused by violent muscular efforts too nearly resemble the ordinary cases of fracture (particularly fractures of the patella) to call for any remark here; and the treatment of the fracture in the cases which occur during the progress of known disease is a matter usually of subordinate importance, and has been already sufficiently discussed in treating of the disease. I would merely add, that when the long bones are perforated by ulceration occurring around a sequestrum, the question of amputating the limb, or attempting to save it, will demand much care, and that, as a general rule, amputation will not be required in the upper extremity, nor should it be performed in the spontaneous fracture which rather frequently follows acute necrosis in children, unless the general health is evidently giving way; but in other cases of necrosis of the bones of the lower limb, and in almost all cases of ulceration not due to the separation of a large sequestrum, amputation as a general rule is indicated. When fracture occurs during the ordinary muscular exertion of every-day life,[1] and in persons not known to labor under any disease, various remote causes have been imagined, but none have been proved to be really efficient. The one most commonly admitted is syphilis; but, not to dwell on the fact that the accident has occurred in many persons in whom the strongest reason existed for believing that no such taint was present, all that we know of the action of syphilis on the bones tends to show that (apart from ulceration and the separation of necrosed portions) it renders them not more but less brittle. The practical point of chief interest connected with such cases is, that there is no reason to despair of union, and that they should be treated in the ordinary way, with perhaps more than the ordinary care to avoid constriction of the soft parts.

[1] Med.-Chir. Trans., vol. xx.

[2] See a preparation in St. Thomas's Hospital Museum, series c, No. 2. Here the atrophy is most marked in the *upper* part of the shaft; and the fragments included between the fractures (which were triple) are thicker than either of the portions of the shaft.

[3] Surgical Treatment of Diseases of Infancy and Childhood, 2d ed., p. 238.

[1] Some interesting cases are to be found in Robert, Conf. de Clinique Chir., 1861; and many are scattered about in various books and periodicals. I remember seeing at St. George's Hospital a stout, florid young man, who had fractured his thigh in simply walking across his room, without catching his foot or making a false step. It healed like any other fracture.

Wounds of Bone.

It is not necessary here to dwell upon wounds of bone, since the reader will find all that is practically important in the essays on Fractures, Gunshot Wounds, and Injuries of the Head. Cases of incised wounds of bone without fracture do, it is true, occasionally come under the notice of the surgeon. The chief interest in such injuries lies in the probability of diffuse suppuration (osteomyelitis) supervening, or of the separation of the periosteum, which is a common event in such cases, leading to necrosis. A reference to those sections will illustrate sufficiently the prognosis and treatment.

ON EXCISION OF BONES AND JOINTS.

By T. Holmes, Esq.

Revised by John H. Packard, M.D.

Excisions in General.

The operations which are to be described in the sequel are all of modern introduction into practice; for although scattered passages are found in the writings of the medical authors of antiquity, which have been held to prove that they were acquainted with the possibility of dissecting out diseased or injured bones, it must be allowed that such passages are in many respects dubious; and it is at any rate certain, that operations of this kind were very rare in olden times; that no rules were laid down for them in ancient surgery; and that they had altogether passed out of notice before the revival of surgery as an art founded on rational principles.[1] When this had once happened, an attempt to preserve a limb by removing only the diseased portions of bone was so reasonable, that it was sure to be made; nor will it now be denied by any one, that a large amount of success has attended that attempt.[2]

I propose here, as well as my limits will permit, to treat, *first*, of the general indications for excision of entire bones or of their articular ends, as opposed to treatment without any operation, or to orthopædic measures, or to amputation; and, *secondly*, to describe the operations in use for removing certain entire bones, and the joints which are accessible to such treatment.

In considering the question between excision and what may be termed the expectant treatment, it may be laid down as a general rule, that a large or important joint ought not to be excised while any reasonable prospect exists of a cure without operation; but when bones which are of no great size, and removable by a moderate operation, are extensively diseased, the surgeon may very reasonably propose to cut short the disease by excising the entire bone, while yet he may allow that recovery is not hopeless should the patient's circumstances allow of his obtaining prolonged and judicious treatment; for the result of prolonged treatment is always doubtful, and the most fortunate termination which could be obtained by many months or perhaps years of care will leave the patient's condition little better than the operation from which he will, in all probability, recover in a few weeks.[1] I have had very frequent opportunities of noting the success of operations for the removal of bones of the tarsus and metatarsus, and the superiority of such treatment to that of waiting for a cure—especially in children, whose restlessness renders confinement less likely to be borne. In the hand and wrist, however, such operations are far less applicable.

---

[1] I have not space here to trace the history of excisions from the introduction of the operation by Park and the Moreaus, but would refer the reader for this, and many other points connected with the history and statistics of excision, to a very valuable essay on The Excision of Joints, by Richard M. Hodges, M.D., Boston, U. S., 1861.

[2] Of the success which may attend the practice of excision in properly selected cases, there are some striking instances in the Med.-Chir. Trans. Thus, in vol. lii. of that series, Dr. Humphry reports that he excised the knee in 45 patients, of whom 1 was under treatment, 33 recovered, 2 died, and 9 underwent amputation, of whom 5 recovered and 4 died. Many of these cases were in adults, one being as old as 47. In the same volume Mr. H. Lee contributes a table of 22 cases of excisions of the large joints with only two deaths, both after excision of the knee. Here, however, there was only one patient who recovered from excision of the hip or knee beyond the period of childhood. In vol. liii. Mr. Gant gives an account of 20 cases of various excisions, without a death; 9 of these were excisions of the knee—the eldest 33 years of age—3 underwent amputation; 6 were excisions of the hip—the eldest 26 years of age; the other 5 were cases of excision of the elbow—the eldest 50 years of age. Re-excision was performed in one of the knee and one of the elbow.

M. Sédillot is the chief advocate of an operation to which he has given the name of "l'évidement des os," and which is really nothing else than carrying the usual operation of gouging farther than is commonly done, so as to scrape away the whole interior of the bone, and leave behind (as is presumed) nothing except the periosteum lined by a layer of bone. It must also be presumed that the periosteum and bone so left behind are healthy. I cannot but think that these presumptions are likely to be frequently falsified in practice. If the bone were so extensively diseased as to justify the removal of its entire thickness, I believe either that the periosteum would be easily separable from it, and the whole bone could be removed by subperiosteal resection (as will be detailed further on under the head of excision of the shaft of the tibia), or that the periosteum would also be extensively diseased, in which case the better course would be to excise the whole bone without sparing the periosteum, or to amputate, according to circumstances.

Connected with this part of the subject is the question of the total or partial extirpation of the bone. If the function of the diseased bone be not very important, it is always better to remove the whole of it, since it is often hardly possible in an operation to judge of the real condition of the bone; and if the entire thickness of the bone has to be taken away for any considerable extent, it is very doubtful whether the parts left behind will be of any use; while if the whole be removed, and no osseous tissue be left exposed in the wound, the latter will heal much more readily and probably with less danger of systemic infection.

But the question which far more often perplexes the surgeon is not that between excision and the expectant treatment (except perhaps in the case of the hip), but between excision and amputation. This is so extensive a subject, and so much dependent on the circumstances of each individual case, that I can hardly hope to do more than indicate to the reader the leading considerations which apply to it. They are drawn from numerous circumstances, which may be thus grouped: 1. the situation and functions of the bone or joint to be excised; 2. the state of the patient as to general health, constitutional affection, and age; 3. the nature and extent of the disease; 4. various extraneous circumstances. I will proceed, as briefly as possible, to point out the most common indications for one operation or the other under each of these heads.

1. As to the situation and functions of the bone or joint affected. In the upper extremity, almost any excision which affords a prospect of preserving to the patient the motion of the elbow, of the hand, of the fingers, or perhaps even of the thumb only, is to be preferred to amputation, even although the patient may not recover useful motion in the joint operated on, whether it be the shoulder, or the elbow, or the wrist. There is, however, a limit to the application of this rule, since a limb which swings useless, like a flail, may prove more of an annoyance than an advantage. In the hip the question of amputation for disease does not occur in ordinary circumstances, in any case where excision is possible:[1] and in gunshot injuries, which are almost the only cases in which the operations are pitted against each other, the nearly uniform fatality of primary amputation at the hip, in modern military surgery, gives the surgeon a decided leaning to excision. In the knee the question is more difficult, and the advantages of the stiff limb, left after even the most successful excision, over the artificial substitute (especially in the case of a wealthy person who can afford to purchase the ingenious artificial limbs now manufactured), are not so great as to balance, in the minds of some surgeons, the increased danger to life which (as I fear we cannot help admitting) the operation entails, combined with the risk of failure and of the necessity for consecutive amputation.

---

[1] I would also refer the reader, on this head, to Mr. Johnstone's observations in the essay on DISEASES OF THE JOINTS, in the present volume.

[1] In rare cases amputation at the hip-joint is, I think, justifiable, when the disease extends too far for excision, or the knee is simultaneously affected. The point will be discussed further on.

But excision of the knee is now generally adopted in patients otherwise healthy, when the disease is only of limited extent, so as to be curable by the removal of thin slices of the affected bones. In injuries of the knee, excision has not as yet been much practised, nor has the experience obtained of it been very satisfactory: the injuries to the knee that demand operation in civil practice are generally too extensive for excision, and other reasons usually preclude it in military surgery; but in limited injuries it will occasionally be attempted in both civil and military practice. Below the knee, the excision of large portions of the bones of the leg seems much practised in Germany; but chiefly in necrosis, of which we shall have to speak presently. The excision of the ankle has occasionally yielded satisfactory results in the hands of Mr. Hancock[1] and other operators, amongst whom I may reckon myself; but amputation at the ankle-joint is so much less severe an operation, and so much more sure of success, that even now few surgeons care to attempt excision. In cases of injury the comminuted portions of bone may occasionally be removed, and a useful foot preserved; but no rules can be laid down on this point. In the tarsus, the removal of the os calcis when much diseased or extensively injured is a very successful operation, and one which should always be preferred to amputation. The astragalus, when dislocated, has been excised without much impairment to the usefulness of the foot, and I have on several occasions removed the entire bone in chronic disease with a very good result. The bones of the front of the tarsus are far less favorably situated for excision, since they are all enveloped in the folds of a common synovial membrane, and therefore are prone to participate in each other's diseases; but still, in the cases, which are so common, of caries attacking the cuneiform or cuboid bones, an attempt ought always to be made to save the foot, by removing the bones affected, whenever the disease has not spread too far. When one or two metatarsal bones are extensively diseased, they should be dissected out, the toes being removed at the same time, if the operator thinks fit. I have only had occasion to practise this on the first metatarsal bone, which I have several times removed with very good results, leaving the great toe, which will derive so much support from the next toe as to become extremely useful.

2. With respect to the state of the patient, it may be said, in general terms, that excision of large joints is only to be recommended for patients in good health, not worn out by previous disease or confinement, nor deeply affected with constitutional taint (rickets, struma,[1] rheumatism, or syphilis); nor should such an operation be practised in the joints of the lower extremity, on patients past the middle period of life. In the very early period also, many risks may be run with a view of avoiding excision and preserving the limb entirely; and after the failure of such attempts, the case has usually passed beyond the reach of excision, when amputation becomes necessary. So that excisions are almost exclusively practised in childhood, youth, and early manhood.

3. As to the disease—excision is never to be recommended for the removal of malignant diseases of the joint-ends or other parts of the bone. It is true that such operations have been practised by very good surgeons; but they must be regarded as experimental proceedings, justifiable in the early period of the operation, but contra-indicated by more extensive experience. Nor should excision be practised on account of acute abscess of the knee-joint, and only with much caution in acute diseases of any joint. It is much better to endeavor by free incisions and appropriate treatment to support the patient through this stage, with a view of removing the joint (if the extent of the disease renders it practicable) at a later period; but should the patient's health be giving way under the irritation of acute abscess, amputation is indicated in the knee and ankle, and the prospects of excision in other joints are very much less favorable than in chronic cases. The most appropriate cases for the excision of joints are those of chronic disease of all the tissues ("white swelling"), in which the bones are probably not affected to any great depth—a disease which may be due to a strumous taint, but in which the constitutional affection has subsided or is no longer active. In chronic abscess of bone occurring near the articular surface and making its way into the joint, excision may be practised with every chance of success, provided the abscess is not too far from the joint-surface. Necrosis of the articular surface only is another favorable condition for excision; but in many cases the mere removal of the dead bone will suffice. For excision of entire bones, necrosis of their shafts is the most favorable condition, since the periosteal sheath may be relied on to reproduce the bone to a sufficient extent to restore the functions of the member. In such con-

---

[1] Barwell On the Joints, p. 463.

[1] I have, however, removed the elbow-joint in strumous children with very good results, though there has been extensive strumous disease elsewhere.

ditions whole bones of the upper and even of the lower extremity have been removed, without any detriment to its ultimate usefulness. In extensive caries, on the other hand, amputation is clearly indicated in the lower extremity; while even in the shoulder, elbow, and wrist, though an attempt to preserve the limb when the carious disease extends considerably beyond the epiphyseal ends may not be unjustifiable, it must be allowed to be of very doubtful benefit.

4. The extraneous circumstances which may decide the surgeon to perform amputation, in a case otherwise favorable for excision, refer principally to the lower extremity, and depend on the facilities for after-treatment. Excisions in the lower limb require, in order to have a fair prospect of success, uninterrupted care and unbroken repose, in appropriate position, from the moment of the operation, for many weeks or even months. Hence the great rarity of the performance of excision of the knee in military practice, and the bad success which has attended it. Or the patient's irritable habits and impatience of confinement may occasionally lead to the preference of amputation.

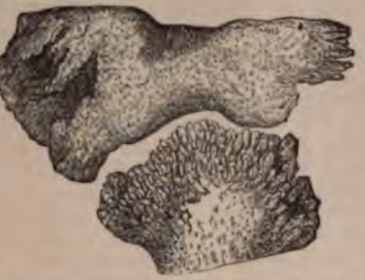
General Observations on the Operations of Excision.

In the resection of any large joint, except the hip and the shoulder, I prefer in ordinary cases to remove the whole articulating surface. Partial excisions, though they appear to succeed well enough in the two great ball-and-socket joints, are repudiated in the case of the large ginglymoid joints by most surgeons of experience;[1] and even in the hip and shoulder many prefer total excision. Hence it is necessary, in the first place, to divide the soft parts freely, in order to be able to turn the ends of the bones out of the wound, and apply the saw above the articular surface. The removal of the diseased bone piecemeal, by scooping out the joint-ends, is a very inferior practice, for it is difficult to judge of the condition of the part left behind, and the union is liable to be very irregular, and will probably be delayed by the separation of numerous small nodules broken away from the bone, but not removed. Whereas, if the end of the bone be well exposed, and a clean section made with the saw, the condition of the bone left behind can be ascertained with almost entire certainty, and the parts are placed in the most favorable circumstances for union. In the upper extremity, where freedom of motion after the operation is sought for, it is desirable to prevent too extensive cicatrization, and especially the adherence of the cicatrix to the bones. Therefore, when the operation is completed, the parts should be carefully readjusted; those portions of the wound in which it is wished to secure speedy union without puckering should be brought together with silver sutures, while free exit for the matter in other parts of the incision is allowed. It must not be forgotten that excisions are not, under ordinary circumstances, performed until the joint has become disintegrated by chronic disease, so that both the tissues around the joint and those which enter into its composition, vary very much from their natural state. Around the joint, the thickening produced by old inflammation, and the burrowing of abscesses and sinuses, tend to obscure the natural relations and appearances of the parts; while in the joint, old dislocation and partial ankylosis may render what would otherwise be an easy operation inordinately difficult, and may even make it almost impossible to recognize the parts exposed. Then, again, the contraction of the tendons, which sometimes accompanies long-continued disease of the joints, may have reached such a point that the limb cannot be placed in the proper position without the aid of tenotomy. In consequence of all these circumstances, the knife must be kept close to the bones when they are reached, in order to avoid any part which it may be desirable to spare, but which the morbid condition of the tissues prevents the operator from seeing; and the surgeon must be prepared to vary his proceeding slightly with the varying condition of the articulating ends of the bones. The operator should be careful not to confound with caries that roughening of the surface of a bone which is produced by healthy periosteal inflammation, spreading from the diseased joint, and often extending to a considerable distance on all sides of it. Such was the case in the instance here figured [fig. 608] where the section has passed through the roughened portions, but the whole of the carious part has been removed. It is quite unnecessary to remove the parts affected merely with its external inflammation. But the whole of the ulcerated and softened bone-tissue must be carefully eradicated. As to the thickened synovial membrane, which so often lies around the diseased joint-ends, it is well, I think, to cut away as much of it as can be removed without trouble or risk; but I have not observed any harm from leaving small portions of it behind. Before the patient has recovered his consciousness, the limb should, in all cases, be carefully secured upon a splint, in the position it is intended to maintain for the first few days after the operation. This position need not necessarily be the one most favorable for ankylosis, except where bony union is desired. In that case the limb ought never to be moved, if it can be avoided, out of the position in which it is intended to ankylose; and the first dressing, or change of splint, after the operation ought to be delayed as long as due attention to cleanliness allows.

---

[1] Some very good surgeons, however, occasionally resort to partial excision of the elbow. See, for example, a case of partial excision of the elbow (limited to the head of the ulna) reported by Mr. De Morgan in the Path. Soc. Trans., vol. xix., 323.

Fig. 608.



Portions of bone removed in an excision of the elbow. From a preparation in the Museum of St. George's Hospital.

As to the instruments required in excisions, little need be said. These operations are no exception to the general rule, that difficulties are better overcome by the dexterous use of common instruments than by the invention of special and often complicated apparatus. The elaborate instruments described, usually in French surgical works, appear to be really intended to save the surgeon from the necessity of thoroughly exposing the bones, by turning down proper flaps, and thus to enable him to remove the bones piecemeal; and if so, their principle is radically bad. The chain-saw, which seems to be much used in France, is hardly ever employed in England, though it may be useful occasionally in deep-seated parts. Some operators like to steady the bone, and guard the parts around, by passing under it a large director, mounted on a handle; and such an instrument may be very convenient when the bone cannot be turned out of the wound. [(Fig. 609.) This is also of use sometimes in facilitating the application of the chain-saw when that instrument is used.] The saw called by the name of its inventor, Mr. Butcher [fig. 610], will often be found useful, but for ordinary purposes I prefer to use a common amputating saw. The large bone forceps, with a double jaw, called by Sir W. Fergusson "the lion-forceps" [fig. 611], are almost indispensable for holding firmly the piece of bone which is to be sawed off. These instruments, together with cutting pliers, a keyhole-saw, gouge, chisel, trephine, blunt [and cut-

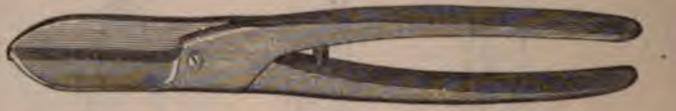
Elevator.

ting] bone forceps [fig. 612], and curved spatulas, are all the special apparatus necessary.

[A strong scalpel, such as is shown in fig. 617, having the end of the handle armed with a blunt steel edge, is often very useful, the latter part being employed to detach the periosteum from the bone to be cut through, or blunt periosteum knives, such as shown in figs. 618 and 619, may be used. Besides the gouge forceps, a burr set in a handle (fig. 620) will serve to rasp away portions of carious bone which could not be otherwise reached. And the ordinary elevator (fig. 621), such as is found in sets of trephining instruments, will be found very useful in prying up sequestra so as to catch them with the forceps.

[Mr. Butcher has also devised a very excellent "knife-bladed cutting forceps," represented in fig. 622. For shearing off small portions or edges of bone, this is sometimes extremely convenient.

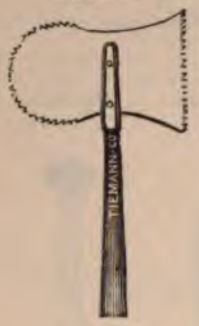
Fig. 622.



Complex instruments are as objectionable in these operations as in all others, but it is worth while for the surgeon to have the best forms of simple tools, and to be provided with suitable appliances for the purposes in hand.

Hey's saw (fig. 623), is sometimes useful in dividing bridges of bone which prevent the ready extraction of sequestra.]

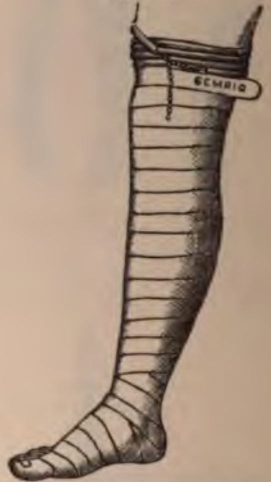
Fig. 623.



The bones to be removed ought always to be taken away as clean as possible, and if, in removing entire bones or portions of their shafts, the periosteum can be left behind, it will no doubt be an advantage, as tending to give more firmness to the cicatrix.

[Esmarch's elastic bandage may often be employed in operating upon the bones of the extremities with advantage. The mode of applying it is by enveloping the limb completely and firmly with successive turns, then encircling it above with a rubber tubing tightly drawn, and removing the bandage itself. The limb will be found bloodless and corpse-like, and can be operated on without hemorrhage. It is said that troublesome secondary bleeding sometimes occurs after the removal of the tubing, but the free use of *very hot* water would probably prevent this. I have never met with anything of the kind.

Fig 624.



Esmarch's bandage applied.]

Subperiosteal Excision. — The general question of subperiosteal resections has lately been brought into much prominence by the labors of M. Ollier, and by the interesting work which he has published on the subject.[1] The operator will find that in many conditions, at any rate, of disease —possibly in most of those in which he is called upon to operate, and in many subjects previously healthy, especially in early life—the periosteum can be stripped off the bone with moderate facility, by using raspatories or chisels with somewhat blunted edges, such as are figured in M. Ollier's work.[2] When this has been done a chain-saw can be insinuated between the detached periosteum and the bone, and the latter removed almost or altogether clean. In amputation of the thigh I have frequently dissected off a sleeve of periosteum from the femur before sawing it through—using this periosteum to cover the section of the stump of the bone; and in many other regions of the body I have convinced myself of the ease with which the periosteum may be entirely separated from the surface of the healthy bone. In many diseased conditions the separation is made still more readily. In fact, in necrosis, and in the advanced stages of caries, the periosteum separates from the bone almost spontaneously. There are other conditions (those in which active inflammation is still in progress, but has not proceeded to suppuration) where the periosteum adheres too closely to the bone to be separated without an amount of tearing and violence fatal to its integrity, and in such conditions the attempt if commenced ought to be abandoned.

---

[1] Traité experimental et clinique de la Régénération des Os. Paris, 1867.

[2] I am quite ready to admit, if it is a matter of any moment, that in the former edition of this work I had over-estimated the difficulty of detaching the periosteum in a continuous layer. Subsequent experience in several cases on the living subject has convinced me that this is not only possible, but easy in a great number of cases.

There are various advantages and disadvantages connected with the preservation of the periosteum in excision. The bone will be reproduced to a certain extent at least, and perhaps entirely.[1] This reproduction will give firmness to the cicatrix in case of excision of an entire bone, will fill up the gap and add length to the limb in case of resection of a portion of the entire shaft of a long bone, and will reproduce the articulating portions and the processes for the attachments of muscles around an excised joint. Again, since in the subperiosteal proceeding, the tendons of the muscles are detached entire from the bone, they will not be so much injured as in the ordinary operation, and will probably obtain better leverage. Finally, as the instrument is kept all the time close upon the bone, there is much less risk of injury to the neighboring vessels and nerves. On the other hand, the operative proceeding is long and tedious; it is difficult to remove the bone without detaching the periosteum to some extent from the part left behind; if the periosteum is much handled, it is liable to slough, which delays the healing of the wound and endangers the success of the reparative process; and the reproduction of bone is by no means an undoubted benefit—in many cases is certainly undesirable. Subperiosteal resection, therefore, appears to me inapplicable in several of the special excisions, as will be pointed out in the sequel.

EXCISIONS IN PARTICULAR.

Excision of the shoulder, as the term is ordinarily used, is intended to signify merely the removal of the head of the humerus. The operation is practised in preference to amputation at the shoulder-joint in cases of gunshot wound or compound dislocation, when the injury is not too extensive; and is the only operation admissible in chronic disease of the joint. But in cases of rapidly growing tumor of the head of the bone, amputation would seem the more prudent course; and still more so, if the tumor were known to be cancerous. In ankylosis—an affection which is rare in the shoulder—no cutting operation is justifiable.

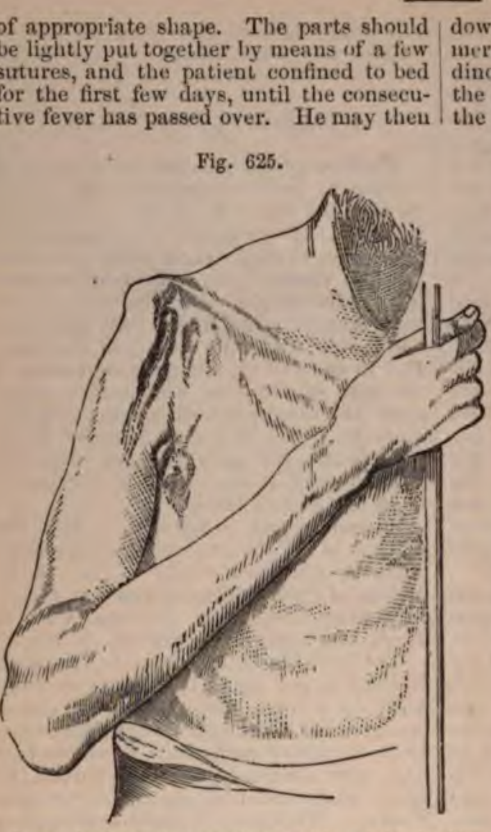
[Subcutaneous osteotomy, after the method of Mr. W. Adams, has been done with an excellent result by Dr. J. E. Mears, of Philadelphia, in a case of anchylosis after dislocation. (Trans. Coll. of Phys. of Phila., N. S., vol. iii., p. 199.)]

The head of the bone may be removed, if there is not much thickening over the joint, by a single incision running downwards as far as may be judged necessary from the upper part of the acromion process, over the most prominent part of the head, where it is most plainly felt beneath the skin. This line of incision corresponds pretty nearly to the direction of the long tendon of the biceps muscle. In some cases it is necessary to make a flap out of the deltoid muscle, of a somewhat triangular shape, with its base upwards. The precise position of the incisions which bound this flap is a matter of secondary importance, and is usually determined by that of the sinuses or wounds. The head of the bone, having thus been exposed, is to be rotated (when the shaft is entire) first outwards, in order to stretch the tendon of the subscapularis, then inwards, to make tense those attached to the greater tuberosity; these tendons are to be divided, and the capsule thus freely opened, and then the head of the bone is to be thrust out of the wound, and sawn off. If the case is one of injury, and the head of the bone is severed from the shaft, it must be seized with the lion forceps, and dissected out. The bleeding is usually free, from the posterior circumflex artery or its branches. If the long tendon of the biceps can be distinguished, it should be spared. In both disease and injury, the glenoid cavity often escapes; but if it should be found affected, it may be thought necessary to remove it. This is best done with a large chisel, or with bone-nippers of appropriate shape. The parts should be lightly put together by means of a few sutures, and the patient confined to bed for the first few days, until the consecutive fever has passed over. He may then be allowed to move about, the elbow being carefully supported. The tendency of the muscles, which form the flaps of the axilla, to displace the bone may be counteracted by a pad in the armpit.

---

[1] One of the most striking instances of this reproduction is found in the account by M. Doutrelepont of the dissection of a specimen of subperiosteal excision of the elbow, which will be referred to under the head of Excision of the Elbow.

Fig. 625.



Drawn from a patient on whom excision of the shoulder-joint had been performed with success many years previously; to show the position of the wound, the shape of the shoulder, and the atrophy of the deltoid and of the upper arm generally

M. Ollier believes that the sub-periosteal method is even more applicable in the resection of the head and upper part of the humerus than in any other excision, and has given a very interesting instance of its successful performance in a case where, besides the head of the humerus, more than four inches of the shaft were removed.[1] The resulting shortening did not exceed half an inch. The sub-periosteal excision of the shoulder is not so difficult as some of the other similar operations. An incision being made in a somewhat longitudinal direction through the anterior part of the deltoid muscle[2] down to the bone, the head of the humerus is fairly exposed, and all the tendinous and fibrous structures (including the periosteum, the tendons attached to the greater and lesser tuberosities, and the capsule of the joint), are gradually separated from the bone by the sharp and blunt raspatories. The bone can then be pushed out of the wound, and if it is to be divided lower down the operator proceeds to denude it to any required extent by pushing it upwards out of its periosteal sheath until the saw can be applied. M. Ollier has now practised this operation four times, and in all cases with success, removing two and a half inches of the shaft in one instance, and more than four inches in the case above referred to.[1]

The amount of bone which may be removed in cases of injury, with a prospect of preserving a useful limb, appears to be considerable. Four or five inches of the bone have been removed with good result.[2] But no doubt the less that can be taken away the better. In cases of injury, provided all the comminuted portion is removed, fractures or fissures running down from the chief seat of injury may be disregarded. In chronic disease of the joint, the affection is usually limited to the head, except in cases of necrosis; but in necrosis it is more usual to find the shaft only diseased, and the joint exempt.[3]

The amount of motion obtained after the most successful resection of the head of the humerus does not seem so great as that which is recovered in some cases of ankylosis after disease. The arm can never, as it seems, be elevated beyond the horizontal line; while in many cases it hangs

---

[1] Case of Louise Gaillard, op. cit., vol. ii., pp. 46 and 514.

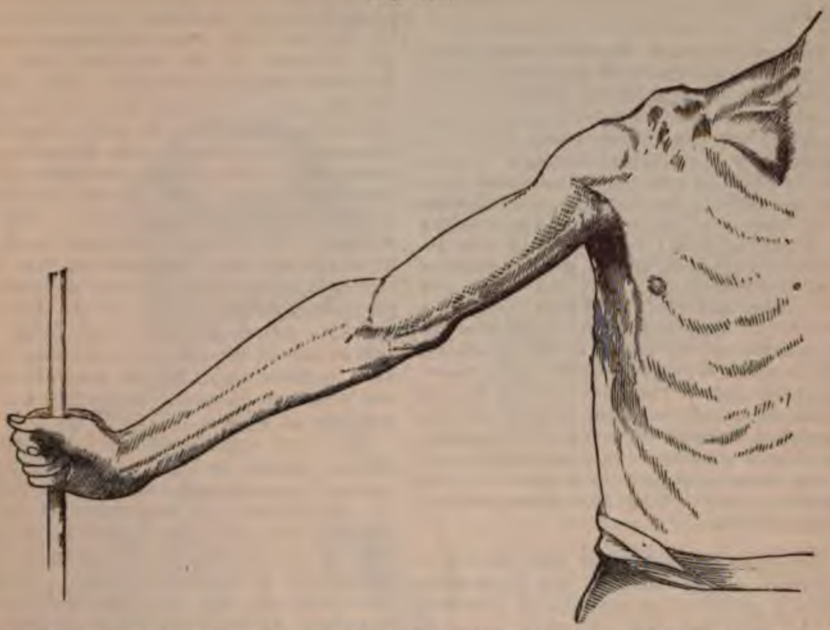
[2] M. Ollier attaches much importance to the preservation of the major part of the deltoid in connection with its nerve—the circumflex. For this purpose it would be desirable to make the incision between the deltoid and pectoralis major, but for the wound of the cephalic vein which this would involve. It is in order to avoid this injury that M. Ollier sacrifices a small part of the deltoid muscle. Other operators, as Nélaton, recommend a transverse incision.

[1] Des Resections des grandes Articulations. Lyon, 1869, p. 15.

[2] Hodges, op. cit., p. 26; Ollier, sup. cit.

[3] In the celebrated case of White of Manchester, usually quoted as the first in which excision of the shoulder was performed, a large sequestrum was removed; but it does not appear that that sequestrum involved the joint; in fact, the plate in White's Cases in Surgery, fig. i., p. 68, clearly shows that the shaft had separated from the epiphysis, and that the part removed was the necrosed upper portion of the diaphysis.

Fig. 626.



From the same patient as fig. 625, to show the extent of motion obtained. It will be observed that the deltoid, though atrophied, has not entirely lost power.

down, without any power whatever in the deltoid, at a greater or less distance from the scapula. But the movements of flexion, extension, and adduction are usually free; abduction can often be effected to the extent of raising the arm considerably from the side; and there is usually sufficient power in the forearm to carry heavy weights, and perform many of the ordinary domestic tasks. This was the case in the patient from whom figs. 625–6 were drawn. The arm is therefore a very useful one, irrespective of the vast importance of preserving the hand; and the patient is enabled to follow many of the ordinary trades. It does not appear that any advantage is gained by removing the glenoid cavity; while, as far as can be judged,[1] the operation is rendered more severe and more dangerous to life. Hence, unless disease is clearly present in that part, it should be let alone. "The average length of time," says Dr. Hodges, "before some use of the limb was commenced, as calculated from thirty-one of the cases in my table, was over four months; a much longer period than this was required, however, to elapse before the limb could be said to become really serviceable." The table in Dr. Hodges' treatise contains fifty cases, eight of which died, and in four others the operation was unsuccessful.

[Prothetic apparatus, such as is shown in fig. 627, may be employed to great advantage in increasing the usefulness of the arm after excisions of the head of

[1] See the cases quoted by Dr. Hodges, op. cit., p. 34. Of the fatal cases there reported (eight in number), there was but a single instance of death where the glenoid cavity had not been interfered with.

the humerus, or of the bone in its continuity.]

The results which M. Ollier obtained by the sub-periosteal method in the only case of excision of the head of the humerus alone which he records, though very good, are not markedly superior to those which have been obtained by the ordinary method.[1] In the case in which he removed the head and about half the shaft of the humerus, the following is his account of the result. "The shoulder is of rounded form; not only is the bone reproduced in length, but the scapulo-humeral joint is reconstituted. The end of the new bone articulates with the glenoid cavity by a joint of the enarthrodial type—that is to say one capable of movement in all directions. All the muscles of the shoulder have recovered their action. The deltoid, which in most of the old operations remained atrophied and paralyzed, is capable of energetic contraction. The rotator muscles are inserted on to the end of the reproduced bone, by means of the old capsule, with which they have preserved their former relations."[2]

Excision of the scapula and clavicle.—Excision of the scapula has been occasionally practised on account of necrosis, or the bone has been removed, together with a tumor growing from it: the excision, however, in the latter class of cases has usually been only partial, *i. e.*, only the portion of the bone implicated in the tumor has been removed. The operation in such cases has usually been protracted and bloody;[3] and it may be added that in most of the published cases it was of very doubtful benefit; the tumor being either of a malignant nature, and returning in spite of the operation, which did not seem to prolong life; or else being dependent on syphilis, and very probably curable without any operation at all.[4] These considerations—added to the great severity of the operation in cases of rapidly-growing tumor, where the large arteries which surround the scapula on all sides are enlarged for the supply of the new growth—ought to make the surgeon very cautious in recommending such operations. The operations on the scapula for necrosis, like all other operations for this affection, have turned out much more satisfactorily; but they bear more resemblance to the usual proceedings for the extraction of sequestra than to formal operations for excision. A case related by the late Mr. Jones, of Jersey, in the 42d volume of the Medico-Chirurgical Transactions, will illustrate these observations, and will show what useful motion may be preserved even after the removal of a sequestrum involving almost the whole scapula, inclusive of its articular surface. No special directions are needed for these operations. The position of the sinuses will point out the most convenient directions for the incisions, which should be kept as much as possible upon the limits of the bone, in order to avoid as many of the large vessels as can be spared. The bleeding, however, in these operations for necrosis seems far less than in those performed for the removal of tumors.

The total excision of the scapula for a tumor should be thus performed. The patient being brought under the influence of chloroform, an assistant should be charged with the compression of the subclavian artery; for which purpose, if the projection of the tumor makes compression difficult, the incisions may be so managed as to enable him to put his finger directly down upon it. This precaution much diminishes the hemorrhage from the subscapular artery and its branches, which otherwise might be formidable. The surgeon then proceeds to denude the tumor of its outer coverings by turning down appropriate skin-flaps, taking great care, however, not to open the capsule of the tumor itself.[1] When the whole tumor is thus exposed, the muscles inserted into the vertebral border of the bone should be rapidly divided, as also those which are attached to the spine of the scapula. The tumor being now movable should be lifted well up, and freed from its other attachments by rapid strokes of the knife, commencing from its *lower* angle. The subscapular artery is divided near the end of the operation, and can be caught hold of by the surgeon or his assistant, and held till the tumor is removed, or can be at once tied. The ligaments of the shoulder are then easily divided and the mass removed.

The acromion process, if not diseased, may be divided with bone-nippers, and left behind to preserve the shape of the parts and protect the head of the humerus.

In this way I have seen the scapula removed with a very large and vascular tumor, without any serious bleeding.

Mr. Syme appears to have been the first surgeon who attempted and successfully performed this severe operation,[1] in the year 1856. The published cases, as far as I know, are twelve in number, five of which have died.[1]

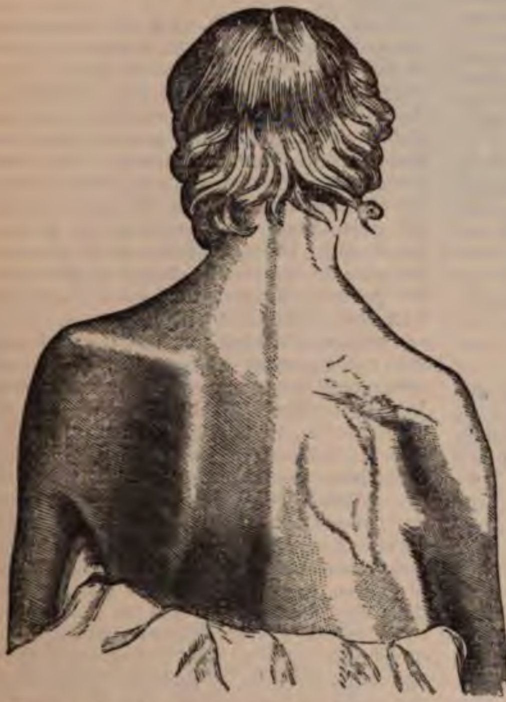
Fig. 628.



Drawing from the photograph of a patient on whom excision of the scapula had been successfully performed by Mr. Pollock. (From St. George's Hospital Reports, Vol. IV.)

The resulting deformity is very slight, especially if the acromion has been left behind to preserve the shape of the shoulder, as was done in the case from which Fig. 628 was drawn. The patient was under Mr. Pollock's care at St. George's Hospital.

Almost the same general observations will apply to the excision of the clavicle as to that of the scapula—only, as the relations of the clavicle are far more important than those of the scapula, so must even greater caution be exercised in undertaking its removal. It is not only that very large vessels lie in the neighborhood, which it may be difficult to avoid during the removal of a large tumor passing into the root of the neck, and perhaps lapping over them; but also that the removal of such a tumor from below the deep fascia of the neck involves alarming risk of death from diffuse inflammation. The benefit to be derived from such an operation ought therefore to be most clearly proved before its dangers are encountered.[1] In operations for necrosis the proceeding will be far more simple, and is likely to be far more successful. The sequestrum will probably be separated from the subclavian vein and the deeper parts by a deposit of new bone, and the patient will have a fair chance of permanent recovery. In operating on the clavicle for a tumor, the incisions should be made very free, one over the long axis of the bone, joined by others in appropriate places for turning down such flaps as may appear necessary, and the parts to be operated on should be brought fairly into view before the bone is meddled with. After having freely divided all the superficial attachments of the bone and tumor, the next step is to divide the outer end of the clavicle from the scapula, either by cutting through the joint or by severing the bone with a small saw or nippers. Then the part which is to be removed can be raised, and must be separated with great care from the important parts which lie below it, so as to reach the sternal part, which is the last divided, and which serves during the operation as a pivot on which the bone can be moved and supported; or, in other cases, it may be found more convenient to divide this part of the bone also at an earlier period of the operation.[2] It appears that very useful motion may be recovered after the removal of a large part, or even the whole, of the shaft of the clavicle.

After amputation at the shoulder-joint, the scapula has been extirpated for recurring disease, and portions of the clavicle have been simultaneously removed. One case is on record in which Mussey, of Cincinnati, removed the whole clavicle and scapula for a tumor recurring after amputation at the shoulder-joint.[3] The patient survived the operation, and was heard of in perfect health thirty-four years afterwards at the age of seventy-one.[1] No directions can be required for the performance of an operation which must vary in its steps according to the condition of the parts left behind after the amputation. Mussey commenced from the inner side, so as to expose and tie the subclavian artery early in the operation; and this would probably be the best course if the state of parts should allow of it. He nearly lost his patient from the passage of air into the subclavian vein.

---

[1] Ten cases are referred to in the New York Med. Journ., 1866, and in the New Syd. Society's Biennial Retrospect for 1865–6, p. 220. Three of these died. Another case is related in Mr. Pollock's paper in the volume of the St. George's Hospital Reports, and one under Mr. Sydney Jones's care in the Lancet for Nov. 21, 1866. Both of these latter proved fatal.

[1] In Mott's case the operation lasted *four hours*, and thirty vessels were tied. Mott says, "This operation far surpassed in tediousness, difficulty, and danger, anything which I have ever witnessed or performed."

[2] See Travers, in Med.-Chir. Trans., vol. xxi.

[3] Am. Jour. of Med. Sci., vol. xxi.

Excision of the elbow for disease may be thus performed. The bones are exposed by a free vertical incision, running parallel and a little external to the ulnar nerve, about four inches in length, having its centre opposite the tip of the olecranon. This suffices for all ordinary cases. If more room is required, the vertical incision may be crossed by one running outwards from its centre. I have not for many years used the old **H**-shaped incision. If, however, this method be adopted (as may, perhaps, be occasionally advisable in cases accompanied by much thickening or by firm ankylosis) two lateral incisions should be made running over either condyle, and united by a transverse cut across the olecranon process. The flaps should then be thrown back and the ulnar nerve dissected out [and held aside by means of a blunt hook]. In the ordinary operation with a single incision, if the head of the radius is found dislocated on the back of the outer condyle (a very common condition in chronic disease of this joint), it may be removed at once with the bone-nippers. The joint should now be freely opened by dissecting round the olecranon, care being taken to keep the edge of the knife close against its inner side, in order to avoid the ulnar nerve, which is usually hidden from view amongst a mass of indurated cellular tissue. The end of the humerus should then be cleaned and turned out of the wound, the lateral ligaments being freely divided; the tip of the olecranon having been previously cut off, if necessary. However slight the disease in the bones may be, the whole end of the humerus just above the condyles ought to be removed. Afterwards the sigmoid cavity of the ulna should be sawn away. It is better, when it can be done without inconvenience, to make the sections of the two bones of the forearm on the same level. The wound should be brought together lightly. The limb should then be lightly bandaged on an angular splint, before the patient is restored to consciousness.[2] If troublesome hemorrhage occurs from the articular arteries at the beginning of the operation, an assistant should compress the brachial, and any vessel which continues to bleed after the removal of the bones should be carefully secured.

Ollier, Langenbeck, and others endeavor to preserve the periosteum in this excision.[1] For this purpose, after a free longitudinal incision over the olecranon, the periosteum is also to be freely incised and separated from the olecranon with a blunt or half-blunt instrument; then the tendon is to be carefully separated from the olecranon, leaving it still attached to the periosteum and surrounding fascia. In exposing the rest of the bones similar precautions are to be taken to preserve the periosteum and tendons in relation with each other and with the fascia. The advantages claimed for this method are that more perfect reproduction is said to ensue, and with more extended motion. Dr. Huëter asserts that the new joint is even provided with synovia, and he says that the movements of the new joint are sometimes more extensive than those of the natural elbow. Thus in one case the patient could lay the flat of his hand on the shoulder of the side on which excision had been performed, which was, of course, impossible on the sound side. This fact, however, seems to me rather to show the absence than the abundance of reproduced bone, and I shall show that the same freedom of motion exists after the ordinary operation. In M. Ollier's work the reader will find the most ample details on the "manuel opératoire," and on the results of this subperiosteal method of excision. His method of operation differs, though only very slightly, from that of Langenbeck. He gives a table of twelve cases operated on in the hospitals at Lyons.[2] Three of these died—a large proportion—due, as he believes, to the unhealthiness of the hospitals in which the patients were treated. In two of the other cases, the time which had elapsed was insufficient to allow of an opinion on the result. All the others had good movement, though in one (M. Dron's case) it seems to have been limited. One of the patients died (of scarlet fever) eight months after operation; but unfortunately an examination of the new joint was not obtained. It must be admitted, therefore, that the only perfectly convincing proof of the reproduction of the articular ends is still wanting in this series of cases. M. Ollier is, however, perfectly certain of the reproduction of a bony mass replacing the olecranon in most of the cases, and of the attachment of the tendon of the triceps to this bone; and also, in some instances, of the reproduction of bony projections from either side of the end of the humerus, giving great lateral stability to the joint. On the whole, therefore, I think we are entitled to conclude that the subperiosteal resection of the elbow, though more laborious than the older methods and requiring more time for its accomplishment, has occasionally yielded excellent results, and deserves to be tested by more extensive practice.

[1] Health; its Friends and its Foes. Mussey, p. 352.

[2] Some surgeons—and among them, I believe, Mr. Syme (see his treatise on Excision of Diseased Joints, 1831, p. 70)—merely flex the arm, and apply a roller; but the support of a splint appears to give confidence, and to prevent spasmodic movements; it need not be applied at any particular angle, but merely in such a position as avoids tension on the sutures.

[1] I would refer the reader on this head to Huëter, in Langenbeck's Archiv, vol. viii., pp. 135 et seq.; Lücke, Aphorisms of Military Surgery, etc., p. 126; Stokes, in Dublin Quarterly Journal, May, 1865; and especially to Ollier, Traité expérimental et clinique de la Régénération des Os. Paris, 1867, vol. ii., pp. 338 et seq.

[2] A somewhat larger number of cases is given in M. Ollier's more recent publication, Des Resections des grandes Articulations—nineteen cases, with four deaths, which, however, were all in adults. Out of eleven cases under 30 years of age, none died.

My own experience of this method is limited to a single case,[1] in which, although it was a very good case for excision, and no bad symptom followed the operation, the motion ultimately obtained was considerably less than in a perfectly successful operation after the ordinary manner; and this appeared to me to depend on the excessive reproduction of the excised olecranon. M. Doutrelepont[2] has published an account of the dissection of a case in which this operation had been successfully performed at the age of 18, about four years before death. In this case the olecranon and coronoid process of the ulna, the head of the radius, and two-thirds of an inch of the humerus, were removed, the section of the latter bone running through the condyles. The drawings attached to M. Doutrelepont's paper show that the condyles of the humerus had been entirely reproduced—the internal condyle rather exuberantly, forming a deep groove for the ulnar nerve. The olecranon was also reproduced, and was longer and more curved than natural—a circumstance of much importance. The head of the radius was also reproduced, and was united to the ulna by an orbicular ligament, as in the natural joint. There was a regular joint between the ulna and humerus (an articular surface, surrounded by a capsule, being formed on the summit of the reproduced sigmoid notch), and true hyaline cartilage had also been reproduced. There was no appreciable shortening of the arm, and the muscles were as well developed on that side as on the other. Pronation and supination were almost natural, flexion and extension were perfectly good, but within the limits of 75° to 120° only.

In my own case, also, the limits of flexion and extension are about the same as the above; and here, also, I thought that extension was checked by the excessive reproduction of the olecranon, whereby its point was brought down into the coronoid fossa before the arm had been nearly straightened. M. Ollier has pointed out the danger of this limitation of motion by the curved shape of the new olecranon,[1] and proposes to rectify it by treating the arm in a more extended position than that ordinarily used, with adequate precaution, of course, against ankylosis.

Mr. Stokes, of Dublin, has been so kind as to inform me that he has practised the subperiosteal excision of the elbow five times. The first two operations, in children aged about 10 and 12, did extremely well, the wounds healing rapidly, with obvious reproduction of bone and excellent movement. The third patient died about two months after operation, and there was no opportunity of examining the joint. In the two other cases (adults), the power of flexion and extension was extremely limited—one almost ankylosed.

From all that I have seen and read on the subject, therefore, I must say that the advantages of the sub-periosteal method in this excision are at present doubtful.

The extent of bone which may be removed in an excision of the elbow is considerable; in fact, within the proper limits, it seems as if the more bone is removed, the better is the result. If only the extreme ends of the bones be sawn off, ankylosis will most likely take place; while if the amount above prescribed (viz., the whole condyloid extremity of the humerus and all the sigmoid cavity of the ulna with the head of the radius), or even a little more on both sides, be taken away, free motion may, under favorable circumstances, be expected. An exaggerated idea, however, appears to prevail, of the amount of bone which may be excised with a prospect of preserving a useful limb. This idea has originated from confusing operations undertaken for necrosis with those for injury or chronic disease (caries). In the former, the whole shaft of a bone has often been removed, and a useful limb left. In the latter, especially if the periosteum be removed with the bone, only a limited quantity of bone can be taken away. If the limits above pointed out have been somewhat exceeded, and still at the point of section the interior of the bones is obviously diseased, it is better, if the disease is not in a very advanced condition, to remove all the bone which is quite disintegrated, preserving what is merely softened, and thus give the patient a chance of saving his limb; but if complete disorganization extends far into the shaft, it is, I think, advisable to amputate, although perhaps in a young and healthy patient the operator might be justified in trying the subperiosteal extirpation of the diseased bone. The position of the line of section in relation to the junction of the epiphysis is a matter of subordinate importance in this joint, since it is of much more importance to obtain a flexible but firm union, so as to allow of good motion, than to avoid any amount of shortening of the affected arm.

---

[1] The Practitioner, No. viii., Feb., 1869, p. 65.

[2] Langenbeck's Archiv, vol. x., p. 911.

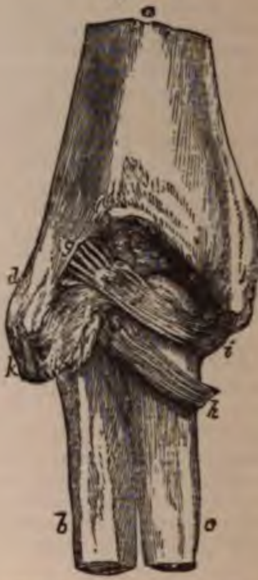
[1] Traité experimental, etc., vol. ii., p. 347.

The arm should be left perfectly quiet for a few days, in the position in which it has been placed after the operation. A good deal of irritative fever often supervenes. When it is necessary to change the dressings for the sake of cleanliness, a grooved splint should be applied, which will lodge the arm and forearm, and which is jointed in the centre and movable by a rack and pinion; with this apparatus, the arm may easily be got into such a position as will afterwards be useful, by gradually changing the angle. Passive motion, however, of a more vigorous kind must not be neglected; the time at which it is commenced varying with the state of the wound and the quantity of the bone which has been removed. If much has been taken away, ankylosis is little to be apprehended; otherwise, at a period which may be roughly stated at about three weeks, daily passive motion ought to be commenced. In the most favorable cases a very perfect false joint succeeds to this treatment; and an amount of motion is regained, which for practical purposes is little inferior to that of the original joint.

Of this a very interesting example is recorded by Mr. Syme, in which he had the opportunity of dissecting the new joint, nine years after the operation, which had been performed on account of injury—the man having in the interval acted as guard on a railway, swinging himself from one carriage to another while the train was in motion, with the injured arm, quite as easily and securely as with the other. The ulna was found united to the humerus by ligament; the end of the radius was polished off, and played on the humerus and on the ulna, a material something like cartilage being interposed. The ends of the bones of the forearm were locked in by two processes projecting downwards from the humerus, and strong lateral, and still stronger anterior and posterior, ligaments also bound them to the latter bone.

Union is, however, seldom so perfect as this, and the bones seem to be united merely by more or less extensible ligament.[1] In these cases, it is said by M. Robert[2] that flexion is composed of two movements; the forearm being first drawn up to the humerus by the triceps, and then flexed by the action of the biceps.

Fig. 629.



Reproduction of the elbow-joint after excision, in Mr. Syme's case. (From the Lancet, 1855, vol. i.), *a*, the humerus; *b*, the ulna: *c*, the radius; *d*, *e*, projections from the shaft of the humerus, locking in the bones of the forearm in the new joint; *f*, new orbicular ligament around the head of the radius; *g*, a portion of the ligamentous union between the ulna and humerus; *h*, tendon of the biceps; *i*, *k*, new lateral ligaments, attached below to the end of the ulna on one side, and the orbicular ligament on the other.

I append drawings from a case in which I excised both elbow-joints of a child aged five, four years since.[3] The drawings show the amount of motion obtained in a perfectly successful case by the old method, and they prove that when the preservation of periosteum is quite disregarded, the same extent and freedom of motion may be obtained as Dr. Hüeter (above quoted) appears to believe to be peculiar to the subperiosteal operation. Mr. Syme's case also shows that considerable reproduction of bone may ensue, by growth from the sections, irrespective of periosteal reproduction. These facts, together with the obvious and proved inconvenience of super-

abundant bony reproduction in this operation, tend still further to make us hesitate in admitting, without further experience, the advantages of the sub-periosteal method.

Osseous ankylosis ought very rarely to occur. If the ulnar nerve be injured, a good deal of wasting of the muscles and loss of motion has been observed to follow, and that even in parts not supplied by the injured nerve; and this fact should make the operator careful to avoid the nerve. On the other hand, cases have occurred to the most experienced operators, in which the nerve was wounded; and one is on record in which it re-united, and no loss of motion or other ill consequence followed.[1] If the patient recover, but with disease persisting or recurring in the ends of the bones, the question of again excising the diseased portions will occur. If necrosis be present, no doubt can exist of the propriety of removing the dead portions, should they be loose; but if the exposed parts of the bone be fixed, or if the disease be caries rather than necrosis, no operation should be performed while the functions of the member appear to be improving. When this is not the case, it is right to try once more to remove the diseased bone before sacrificing the arm. Even a third such attempt has been made, and, as it is said, with good results.

Excision of the elbow is usually considered, and in all probability correctly, as a more formidable operation in respect of mortality than amputation of the arm; but no data exist, as far as I am aware, for a correct comparison between the two. In Dr. Hodges' work there is a table of 119 cases, principally from the journals and other published sources; of these, 15 died; and in 15 others amputation was performed. In the great majority of the cases which survived, the usefulness of the limb was proved by the patient being able to resume his ordinary avocations; but the details as to the extent and kind of motions which resulted are not exact.

---

[1] Syme On the Excision of Diseased Joints, 1831, case viii., pp. 88-94.

In the essays on INJURIES OF THE UPPER EXTREMITY and GUNSHOT WOUNDS the reader will find the indications for amputation, excision, or entire preservation of the limb, in cases of injury. In cases of ankylosis of the elbow excision is rarely required, although where true bony anyklosis has occurred in a bad position, excision may be performed if the patient wishes it; but in bony ankylosis in the flexed position, and in all cases of soft ankylosis, this operation is inadmissible. The former ought to be let alone; the latter are under the control of the methods described in the essay on ORTHOPÆDIC SURGERY. In cases of disease of the bones of the elbow excision is the operation which should be adopted, except under special circumstances necessitating amputation, such as unusual extent of implication of the bones, advanced age, great debility, or constitutional affection. But the rarity of such circumstances is shown by the fact, that Mr. Bryant's collection of 300 amputations[1] only includes 10 in which the arm was amputatated for disease of all kinds. So that excision of the elbow is the operation almost universally resorted to in cases of incurable disease of that joint.

[It may be well to add a few words here in regard to excisions of the elbow-joint in cases of injury. Such admirable results have been obtained in a number of cases in my own experience, that I should not hesitate to substitute this operation for that of amputation, if the great vessels were intact. In the case figured on p. 879, Vol. I., for example, it is very possible that a useful limb might have been obtained in this way.]

Excision of the wrist.—The operation of excision of the wrist has been entirely modified since the first edition of this work, in consequence of the labors of Professor Lister, of Edinburgh, published some years since in the Lancet. He has shown that the failures, to which the old methods of performing this operation usually led, were due in all probability to two chief causes, viz.: (1) a portion of the diseased articular strictures having been left behind, and (2) the tendons having been injured. In order to avoid the former, it is necessary to remove all the bony and cartilaginous structures which enter into the formation of the wrist-joint itself, and of all the carpal joints; viz., the ends of the radius and ulna (which must be divided at a level above the joint between those bones), all the carpal bones, and all the articulating surfaces of the metacarpal bones. In order to avoid the second cause of failure, the operation must be performed through two very free lateral incisions, the tendons being carefully separated from the bones and raised by gradual strokes of the knife with as little violence as possible. For this purpose an incision is made commencing in front over the second metacarpal bone internal to the tendon of the extensor secundi internodii pollicis, and running along the back of the carpus, internal to the same tendon, as high as the base of the styloid process of the radius. The soft parts, including the extensor secundi internodii, and the radial artery, being cautiously detached from the bones external to this incision, and the tendons of the radial extensors of the wrist being also severed from their attachments, the external bones of the carpus will be exposed. When this has been done sufficiently, the next step is to sever the trapezium from the other bones with cutting pliers, in order to facilitate the removal of the latter, which should be done as freely as is found convenient. The operator now turns to the ulnar side of the incision and

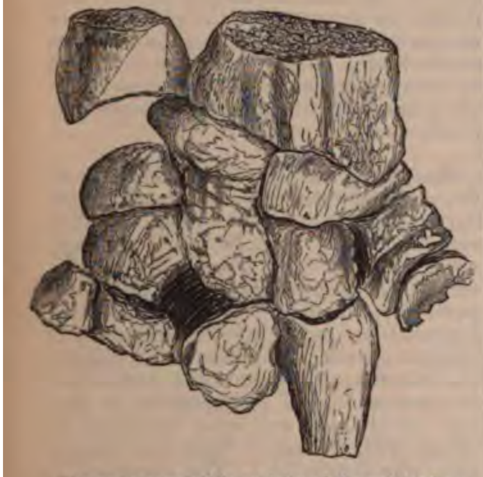
---

[1] Med.-Chir. Trans., vol. xlii.

cleans up the carpal and metacarpal bones as much as can be done easily. The ulnar incision is now made. It should be very free, extending from about two inches above the styloid process down to the middle of the fifth metacarpal bone, and lying near the anterior edge of the ulna. The dorsal line of this incision is then raised along with the tendon of the extensor carpi ulnaris, which should not be isolated from the skin and should be cut as near its insertion as possible. Then the common extensor tendons should be raised, and the whole of the posterior aspect of the carpus denuded, until the two wounds communicate quite freely together; but the radius is not as yet cleaned. The next step is to clean the anterior aspect of the ulna and carpus, in doing which the pisiform bone and the hooked process of the unciform are severed from the rest of the carpus, the former with the knife, the latter with the cutting pliers. In cleaning the anterior aspect of the carpus, care must be taken not to go so far forwards as to endanger the deep palmar arch. Now, the ligaments of the internal carpal bones being sufficiently divided, they are to be removed with blunt bone forceps. Next the end of the ulna is made to protrude from the incision, and is sawn off, as low down as is consistent with its condition, but in any case above its radial articulation. The end of the radius is then cleaned sufficiently to allow of its being protruded and removed. If this can be done without disturbing the tendons from their grooves, it is far better. If the level of the section is below the upper part of the cartilaginous facet for the ulna, the remainder of the cartilage must be cut away with the pliers. The operator next attends to the metacarpal bones which are pushed out from one or the other incision\and cut off with the pliers so as to remove the whole of their cartilage-covered portions. The trapezium bone, which was left in the early stage of the operation, is now carefully dissected out, so as to avoid any injury to the tendon of the flexor carpi radialis or to the radial artery, and the articular surface of the first metacarpal bone is then exposed and removed. Lastly, the cartilaginous portion of the pisiform bone is taken away; but the non-articular part is left behind unless it is diseased, in which case it should be removed entire. The same remark applies to the hooked process of the unciform.

Fig. 633.



The parts removed in excision of the wrist (after Lister).

The operation is one of the most tedious and difficult in surgery, but it appears to me to give very satisfactory results, and therefore should, I think, always be adopted in such cases as are favorable for any operation at all. It is advisable, if not necessary, to put on the tourniquet [or to use the Esmarch apparatus]; so that the view of the parts should not be obscured by the blood. It is also very desirable to break down freely any adhesions which the tendons may have formed, while the patient is under chloroform previous to the operation.

No tendons are divided in this operation except the extensors of the wrist, for the flexor carpi radialis is inserted lower down than the point at which the metacarpal bone is usually divided.

In order to ensure motion, particularly in the fingers, passive movements should be performed from a very early period after the operation. For this purpose, Mr. Lister places the limb on a splint with the palm of the hand raised by a large wedge of cork, fixed below it; so that the joints of the fingers can be moved without taking the limb off the apparatus. Special arrangements are made for keeping the splint steady and for preventing displacement of the hand to either side. Careful and methodical passive motion should be used to each several joint—to those of the finger and thumb almost from the day of operation, and to the wrist as soon as the parts have acquired some firmness, each movement, pronation and supination, flexion and extension, abduction and adduction, being separately exercised; and the patient should be encouraged to make attempts at voluntary motion as early as possible. In order to exercise the fingers, the portion of the splint which supports them may be removed while that on which the wrist is received is still left. Finally, when the rigid splint is left off, some flexible support is still to be worn for a long time.

Partial excisions of the wrist are, I believe, much less promising, although success may be obtained in some cases, especially those of traumatic origin. Thus Mr. West, of Birmingham, has lately published[1] an interesting account of two cases, in one of which he removed the ends of the bones of the forearm and the first row of carpal bones for a disease of traumatic origin. Exfoliation occurred from the carpal bones which had been left behind, and the patient recovered with a moderately useful hand. In the second case, one of rheumatic disease, an abscess had formed in the lower end of the radius; only the radius was excised. The patient recovered, with the powers of writing and of lifting heavy weights.

The operation of excising the wrist, whether totally or partially, is one which I think is seldom advisable, at least judging from my own experience, for, though anxious to test the value of the operation, I have found only one opportunity in six years in which I thought myself justified in doing so. The results in that case were satisfactory. Nor have I seen more than one or two instances in the practice of my colleagues at St. George's Hospital. In spite of the success of the practice followed by Mr. West, I have a strong preference for total over partial excision. But I have no hesitation in saying that these remarks are only meant to apply to the comparison between excision and the expectant treatment. Many cases, I believe, will terminate quite as well if judiciously treated by incisions when necessary, the removal of portions of bone as they become loose, and, above all, the constant and persevering use of passive motion to the fingers, as if excision be practised, and without the risk of operation. But if the comparison be made with amputation, the removal of diseased parts being plainly necessary, then the importance of preserving the hand and fingers, even if much mutilated, is so great that excision is the operation which should in all cases be first discussed, and amputation should not be performed unless the less radical proceeding is absolutely contra-indicated.

Excision of single bones of the hand.—The excision of some of the bones of the hand may be practised with advantage, especially if the tendons are unaffected and can be secured from injury in the operation. It is of especial importance to preserve the thumb by the timely excision of its metacarpal bone or first phalanx when universally diseased; and the benefit of respecting the diseased portion, and leaving the articulating head, is of course still greater. If the periosteum can be spared, there will be in all probability a more firm union between the severed ends of the old bone, in consequence of the production of osseous granules, or even larger pieces of bone, in the cicatrix. It is of little use to remove the phalanges of the fingers (except those of the terminal row), unless in a few cases where they are necrosed and loose, for the formal excision of these bones would almost invariably leave a useless finger. But occasionally, especially when the extensor tendons can be spared, the metacarpal bones may be made the subjects of operation; and here, as well as in the thumb, it is of much importance, if the extent of the disease allows it, not to open either joint, particularly the phalangeal.

No precise directions are necessary for such operations, which consist merely in exposing the diseased bone on its dorsal aspect, scraping off from it all the soft parts, including the periosteum if possible, dividing the bone with cutting forceps (the extensor tendon being held out of the way), then seizing the divided end with the lion-forceps, cleaning the bone on the lower surface, with much care not to dip the point of the knife into the palm, and finally, when the limit of the disease is reached, nipping off the bone. If the extensor tendon has been unavoidably severed, the finger must be carefully supported on a splint till this has reunited. In case of disease of the two middle metacarpal bones, it will be better to remove the diseased portions with a small chisel; and this plan is preferred by many surgeons in the other metacarpal bones also, in order to preserve the periosteum.

Excision of the hip is an operation, of the value of which the most widely differing estimates have been formed by different surgeons. Nor is this surprising, when it is considered that the disease for which it is usually undertaken is accompanied by exhausting and long-continued suppuration, rendering the prospects of surgical operation unfavorable; while, on the other hand, spontaneous recovery is so common that it is impossible in any case which gets well after operation to affirm with certainty that the natural cure was impossible. The operation is performed on account of gunshot wound or in advanced "strumous" disease, accompanied by abscess, where the patient seems in danger of dying of hectic, and the ulceration of the bone is judged to be incurable. The hip-joint ought never to be excised on account of deformity from ankylosis, although it may be advisable in appropriate cases to divide the neck of the femur, or even perhaps to cut a wedge-shaped piece out of it.[1] The operation of excising the hip, as it is commonly spoken of, means merely the removal of the head of the femur: but the acetabulum may also be removed, if it be thought necessary. The operation differs considerably in difficulty, according as the head of the bone is or is not in the acetabulum, and according as the surgeon does or does not require to obtain access to that cavity in order to remove its floor. In most cases of chronic disease the head of the bone has undergone that process of displacement usually, though not very accurately, spoken of as *dislocation*—*i.e.*, the lip of the acetabulum has been ulcerated or absorbed, and the head of the bone (also altered in shape from ulceration) lies partly on the dorsum ilii, partly on the edge of the expanded acetabulum, and is very probably covered by few if any muscular fibres. In fact, in cases of old-standing hip disease, the muscles have become atrophied from disuse, and the ligaments also have in a great measure disappeared. All that is necessary in the operation is to make an incision of sufficient length over the prominence of the bone, running somewhat behind the trochanter, and, having exposed the head of the bone, to saw it off at such a level as the extent of the disease seems to indicate. When, however, the head of the bone remains in the joint, and the ligaments are entire, as is the case generally in excision for injury, and in many of those for disease, the operation is not quite so simple; and it becomes still more difficult if the neck of the bone is fractured, so that the surgeon cannot get any purchase upon the head to turn it out of the acetabulum. In such cases an incision must be made, running behind and parallel to the posterior border of the trochanter, and long enough to admit of free access to the joint. The length will of course vary according to the size of the buttock, but it may be stated in general terms that the incision should commence near the junction of the trochanter and the shaft, and should curve (with its convexity backwards) round the prominent upper border of that process. By cutting now along the neck of the femur, the situation of the joint may be accurately ascertained, if it has been hidden by swelling from disease or injury; and, this having been done, the parts may be divided from within outwards in any direction which may seem convenient (according to the presence of wounds, etc.), so as to render the external incisions crucial or T-shaped. The flaps are now to be reflected. If the neck of the femur is fractured, the fractured part is to be seized with the lion-forceps, and cleared up to the head and round it, and so removed. Search should then be made for shots, foreign bodies, fragments of bone, etc. If, on the other hand, the neck of the bone is entire, and sufficiently strong to bear the requisite force, it may be more convenient to turn

Excision of the hip. (From a case in which the whole floor of the acetabulum, as well as the head of the femur, had been removed several years previously.) To show the position of the wound, the amount of shortening, and the wasting of the limb operated on.

---

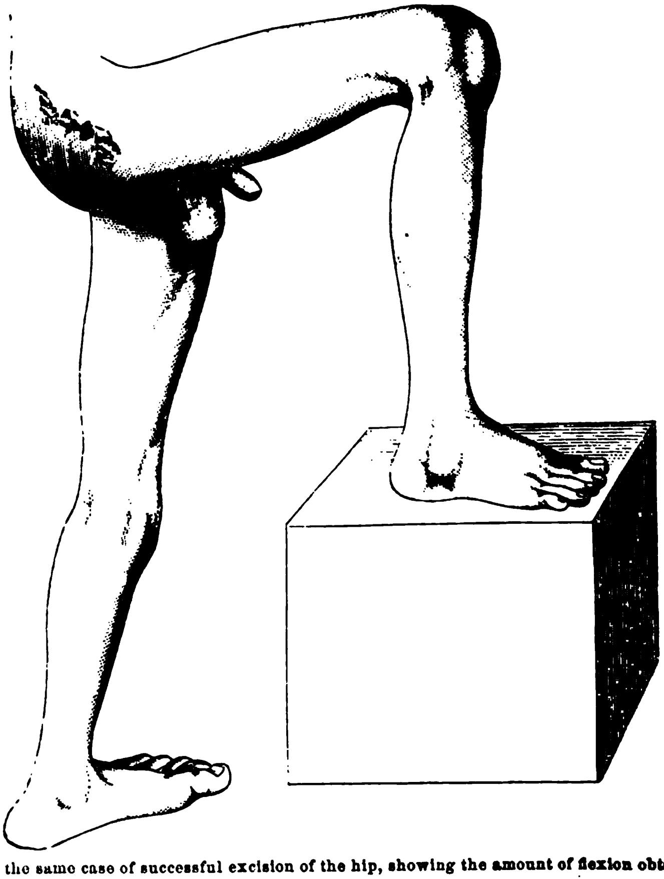
[1] I once saw a case in which the hip was fixed in acute flexion. The symptons induced the surgeon in charge of the case to perform an exploratory operation; but on cutting down, the joint was found free from active disease, but ankylosed. The neck of the femur was sawn through, and the thigh placed on a straight splint. The patient (a child) recovered, with a straight and useful limb. In such cases a subcutaneous operation similar to that practised by Professor Gross on the knee, would probably in most cases be the safest. (See ORTHOPÆDIC SURGERY.)

out the head of the bone, and divide the ligaments, as in ordinary exarticulation; otherwise the neck may be cut through with a keyhole-saw. This instrument should always be at hand, together with a trephine, elevator, gouge, etc., for removing impacted foreign bodies, or for clearing the acetabulum. In many cases the director, mounted on a handle, shown in fig. 609, is very useful. I think it better, whenever the disease does not extend very low down, to preserve at any rate a portion of the trochanter.

Thus far we have spoken only of the removal or decapitation of the head of the femur; but since the acetabulum is freely exposed in this operation, it is possible to carry it further, and remove part, or the whole, of the floor of that cavity; and this has been often done with success.

In Mr. Barwell's treatise on Disease of the Joints, p. 444, the reader will find an interesting account of a case in which Mr. Hancock removed the whole of the floor of the acetabulum, together with the head of the femur; and where, on the death of the patient, nineteen months after the operation (his limb having been useful in the mean time, although some disease still existed in the bones), an opportunity of dissecting the parts was presented. Mr. Erichsen removed not only the whole floor of the acetabulum, but also the ramus of the pubes and ischium, with part of the tuberosity of the ischium and a portion of the dorsum ilii; and reports that the patient had a useful limb.[1] I have obtained a very perfect result in a case from which the annexed figs. (634–37) were taken, where I removed the whole floor of the acetabulum. It is rather inaccurate in such cases to say that the operator has penetrated into the pelvis. A strong fascia still separates the wound from all contact with the viscera or their cellular connections.

Fig. 635.



From the same case of successful excision of the hip, showing the amount of flexion obtained.

The statistics of this operation are of little real value, nor are they of the same

importance as in those excisions where the question lies between the removal of a joint and of a whole limb. The rate of mortality is extremely high; so that out of 111 cases collected by Dr. Hodges,[1] in which the result was known, 56 recovered "with more or less useful limbs," 53 died of the combined effects of the operation and the previous disease, and in the remaining two cases amputation was performed. But it is impossible to deduce any exact conclusion from such facts as these; since, without a personal knowledge of each case, no opinion as to the probability of recovery without operation can be formed. Possibly, more reliable conclusions as to the average mortality of operations may be deduced from the experience of individual operators, though here again there are many sources of fallacy. In my own practice, as stated in a work on the Surgical Treatment of Children's Diseases, out of 19 cases (all children) 6 died from the direct effects of the operation (in one case after amputation); 1 died after the operation from the previous effects of the disease; 1 died of independent disease some time after recovery from amputation; 2 recovered from the operation but not from the disease, and died a long while afterwards; 2 were little, if at all, benefited; 1 (twice excised) was doubtful; 3 had useful limbs, but with sinuses;[1] 3 recovered completely. In Dr. Cheever's essay on "Excision of Joints," in the Reports of the Boston Hospital, 1870, are notes of 11 cases under the care of himself and his colleagues. Two of them were adults, and both died; of the remaining 9, 2 died from tuberculosis, 1 had as yet a useless limb, like chronic hip-disease; 3 had useful limbs, but with sinuses; 1 had a good limb, but was lost sight of; 2 had recovered completely.

Excision of the hip for injury is a far more formidable operation than for disease. For this there are several reasons. The shock of all primary operations is great, and their mortality very high; nor are secondary operations after injury much more favorable. In the hip-joint the operation of excision for disease is very fatal in adult life, and it is only adults who, as a rule, are operated on for injury; and then again a compound fracture laying open the hip-joint is in itself a very severe shock, to which that of the operation is to be superadded. Hence we cannot wonder that the records of this operation should present an appalling death-rate. But then excision is only performed in gunshot injuries of the joint; and in these cases primary amputation is almost uniformly fatal,[2] while the expectant treatment can hardly be said to be much more promising.[3]

In the essay on GUNSHOT WOUNDS, it has been stated that out of eleven cases operated on in the Crimea, in Schleswig-Holstein, and

---

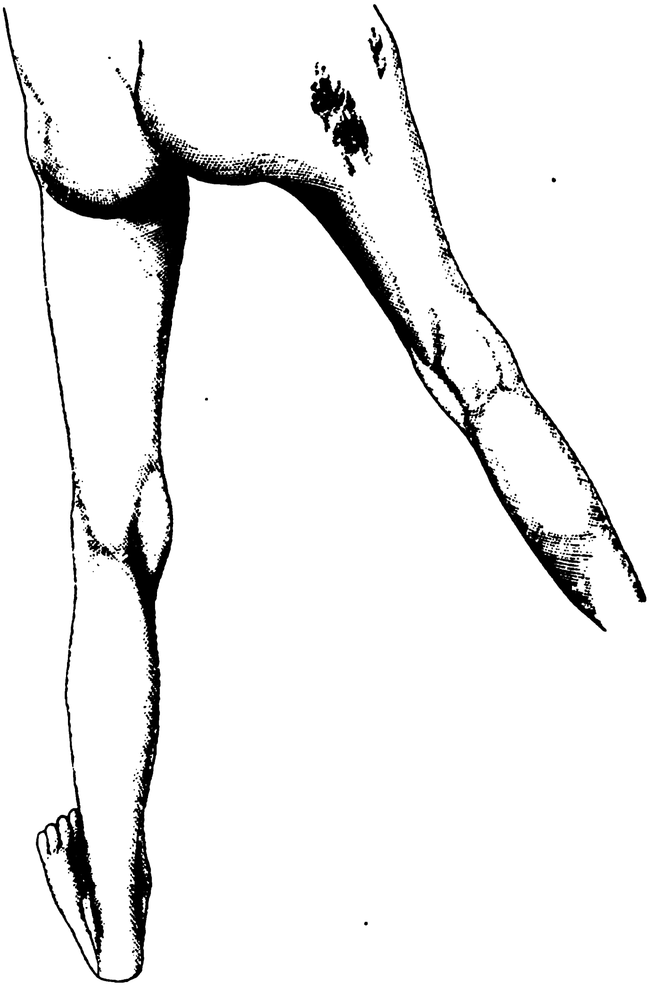
[1] Op. cit., p. 116.

[1] Some, if not all, of these have since recovered.

[2] See GUNSHOT WOUNDS.

[3] In the report referred to in the text, Surgeon Otis, U. S. A., writes: "I continue to share the convictions of Guthrie and the elder authors as to the uniform fatality of such injuries when abandoned to the resources of nature."

Fig. 637.



From the same case, showing the amount of abduction.

in the Italian war of 1859, only two patients survived, and one of these after amputation. Reference was also made to the experience of the American Civil War; but as that reference was necessarily imperfect, since the official documents had not then been completed, I think it would be useful to insert the following summary of Dr. Otis's official report on the subject of excision of the hip-joint for gunshot injury, for which I am indebted to Mr. Longmore's kindness.[1] The whole number of excisions of the hip-joint for gunshot injury known to have occurred during the American war was 63,—48 in the Federal and 15 in the Confederate armies. 32 of these were primary, *i. e.*, performed within 24 hours of the injury; 22 "intermediate," *i. e.*, from 2 to 28 days after; and the remaining 9 "secondary;" the shortest interval being 33 days, the longest nearly 7 months. Out of the 32 primary operations, 2 recovered, showing a death-rate of 93.75 per cent.; 2 out of the 22 intermediate—90.9 per cent.; and 1 out of the 9 secondary;[1] on the whole, 5 recoveries in 63 cases; deaths, 92.1 per cent. Doubtless, the mortality is very high; but viewing the almost necessarily fatal character of the injury, these results may be pronounced satisfactory; and may at any rate encourage a repetition of such attempts. In civil life the opportunity rarely happens; but I remember seeing one case under the care of a former colleague at St. George's Hospital, where I regretted that the operation was not tried. The patient, a young man, in dragging his gun through a hedge, had lodged the charge in the hip-joint, the neck of the femur having been cut cleanly across. He died a few days afterwards from the effects of inflammation and abscess in the joint. The pelvis was uninjured.

---

[1] The facts are abridged from the Brit. Med. Journ., October 23, 1869.

[1] Another successful secondary operation is noticed in the report as having occurred in New Mexico in June. 1868.

The average duration of treatment in those of Dr. Hodges' cases in which the point was noted (49 in number) was 230 days. The high mortality and the very protracted period of convalescence certainly show that, even in many of those severe cases of hip-disease which alone are selected for this operation, the patient's prospects are not materially improved by it, although it must be allowed that the concurrent testimony in its favor of many eminent surgeons, who have had ample opportunities of watching its effects, justify a resort to it in cases which seem otherwise hopeless. The immediate effects of the operation are not often fatal, and it is, to say the least, extremely probable that where there is great and exhausting pain from pressure of the diseased bones on one another, the operation may save life. The greatest care, however, should be bestowed on the diagnosis of any case in which excision is contemplated. There are few instances of advanced hip-disease in which the external surface of the pelvis is not more or less involved. This fact (which may be judged of partly by the direction of sinuses, partly by the grating sensation elicited by passive motion under chloroform) is an unfavorable symptom, but forms no insuperable objection to the proceeding.

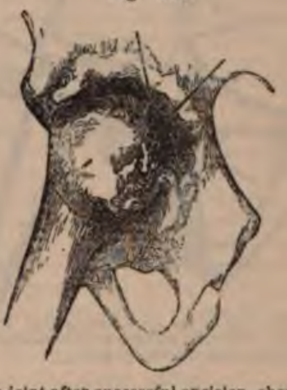
Abscess communicating with the interior of the pelvis near the joint is a still more discouraging symptom. It ought not perhaps to be stated absolutely (as was done in the first edition of this essay) that it ought to forbid the attempt to excise the joint, since it is possible that, by removing the floor of the acetabulum, a sufficient exit will be provided for the matter.[1] But even then the removal of the whole of the diseased bone is very improbable, and the operation must be allowed to be very unlikely to succeed. Abscess communicating with remoter parts of the pelvis, or extensive disease of the femur, or the presence of other strumous affections, ought certainly to forbid the attempt.

Adult age is a serious contra-indication to excision of the hip. A few cases of recoveries after the age of 20 are on record; but as a general rule the operation should be confined to childhood. In one of the successful cases in adult life the operation was performed for chronic osteo-arthritis.

The purport of these indications and contra-indications appears to be that excision ought never to be attempted except in childhood or youth, and never unless, with disease still progressing, the joint-surfaces are hopelessly displaced (a very rare occurrence), or the surgeon, on a careful review of all the symptoms, has strong reasons for concluding that natural recovery is impossible. When the operation is once decided upon, it should not be delayed till the patient's health has given way, but should be performed at once.

The recovery after excision of the hip-joint is very complete, as far as the movements of the limb are concerned, though the shortening is generally, I think, greater than after the spontaneous cure. The preceding figures (634–637) were taken from a lad in whom I excised the hip about five years ago, having removed the floor of the acetabulum so freely that three fingers could be passed through it. Every movement of the limb is perfectly free, and almost as extensive as in the natural condition.

Fig. 638.



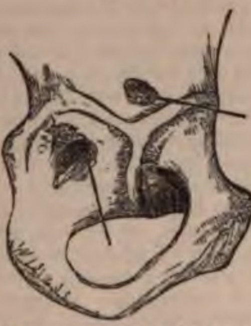
The hip-joint after successful excision, showing the ligamentous cord by which the stump of the femur is united to the pelvis.

Bony ankylosis very rarely takes place. I have never seen it. The annexed illustrations (figs. 638–640), taken from a case where I had excised the hip successfully in a patient who died of another disease, show the usual condition of parts. They correspond closely with the state of things in an interesting preparation in the Museum of the Royal College of Surgeons, taken from the patient, in whom the operation was first performed, by Mr. White.

---

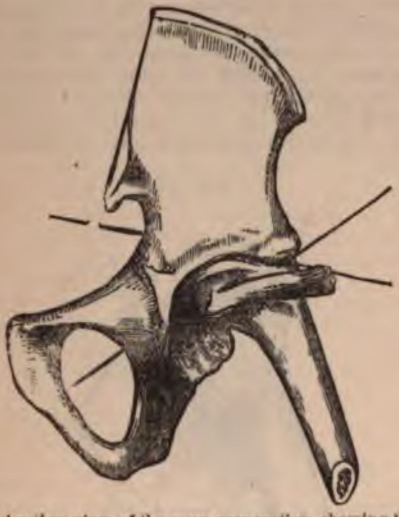
[1] Mr. H. Lee has related a very interesting case in which excision of the hip was attempted; but as the disease in the femur was found too extensive, amputation was performed. There was a large pelvic abscess, which was laid open by freely removing the diseased bone forming the floor of the acetabulum. The patient, a boy aged fourteen, rapidly recovered. (St. George's Hospital Reports, vol. i., p. 149.)

Fig. 639.



From the same case, showing the inner openings of two old sinuses leading through the acetabulum; their outer ends are marked by the bristles in fig. 638.

Fig. 640.



Another view of the same preparation, showing the end of the femur drawn up into the (enlarged) acetabulum by the tendon of the psoas.

Excision of the knee has been practised more frequently than that of any other joint, except the elbow; but the opinions of surgeons are by no means so unanimous on the former subject as they are on the latter; for whereas no one denies that amputation of the arm should only be resorted to in exceptional cases of disease and injury of the elbow, many hospital surgeons, in this city at any rate, think that amputation is advisable in the majority of the affections of the knee. There are many reasons why excision should be less successful in the knee than in the elbow. Firm bony ankylosis is required in the lower extremity; the treatment involves many weeks of strict confinement to one position; the surfaces of bone sawn through are very large; the cavity of the wound is badly situated for union; the epiphyseal lines are near, and if trenched upon in young subjects, the growth of the limb will, in all probability, be checked; the operation is more severe than excision of the elbow; and, finally, the advantage of preserving the foot, although considerable, is far less than that of retaining the hand. It is not likely, therefore, that this operation will ever come into such favor as that on the elbow; still, though it has been vehemently decried, and though its general adoption has possibly been equally retarded by its having been vehemently overpraised, it will always hold a place among the resources of operative surgery for the treatment of appropriate cases.

The acceptance which this operation has met with is not due to its lower rate of mortality. It has been clearly shown by the statistics collected by Dr. Hodges,[1] that in general practice the mortality has been about one-third; a far higher average than that after amputation at the lower third of the thigh for chronic disease of the knee; and from what I can learn of the statistics of metropolitan hospital practice, I believe the same rate of mortality has prevailed.[2] But this only imperfectly represents the ill success of the operation; for if to those who have died we add those whose limbs have been amputated, or have remained useless, we shall find that the failures after the operation at least equal the successes. In spite of this, however, it is the universal conviction of hospital surgeons that the operation ought to be introduced into practice. This conclusion must rest upon other considerations than those of the mere mortality after amputation and excision. It is not very probable that excision of the knee will ever be less fatal than amputation. There is no conceivable reason why it should be so. It is sometimes said that the hemorrhage is less; but I am far from convinced of this. The blood *shed* in an amputation is always greater than in excision; the blood *lost* is frequently less, for in a well-managed amputation the blood which gushes out is only that which was circulating in the amputated part, and little else is really lost to the system. In excision the operation is often a bloody one (though sometimes not so), and secondary hemorrhage is by no means rare. Then it is said that the wound is smaller than in amputation; but though the *surface* of the wound is smaller, its cavity (which is at least as important) is larger. The immediate shock, as far as I have seen, is generally considerable; quite as much so as in amputation.[1] The surfaces of bone exposed are very large, and the union of this great compound fracture, and the filling up of the large cavity left by the operation, call for considerable reparative power, and entail dangers from which amputation is exempt. But what has really brought excision of the knee into practice, and has compensated for the failures induced by its indiscriminate adoption in all kinds of cases, is its striking success in cases which are fitted for it; and it is, therefore, to the discovery of rules whereby such cases can be diagnosed, that the efforts of those who wish to promote this operation should be directed. The space which an adequate discussion of this matter would require not being here at my command, I must be excused for expressing summarily what I believe to be the correct indications for the performance of excision of the knee, as far as our present experience will enable us to lay them down.

---

[1] Op. cit., pp. 142–8.

[2] See Brit. and For. Med.-Chir. Rev., July, 1862.

Excision of the knee should never be performed in elderly persons.[2] They have not usually the requisite reparative power; and the advantage over amputation is not sufficient, even in the most favorable cases, to balance the increased risk. There are many reasons also against performing the operation in very young children:[3] such as the probability of recovery without operation, if the suppurating joint be kept in a good position and freely opened; the risk of checking the growth of the limb by excision; the great probability that the joint-disease is but a symptom of constitutional mischief, in which case excision would do no good. No excision of the knee ought to be undertaken in a patient in whom there is any good reason to suspect, far less any evidence of the existence of, phthisis, or any other constitutional affection. Had this simple dictate of common sense been more strictly adhered to, many of the deaths which now give so gloomy a complexion to the statistical reports of excision of the knee would have been avoided. Excision for disease should be exclusively confined to cases in which the disease is in a chronic condition. In acute abscess the operation is inadmissible. In all cases where sinuses exist, leading for any considerable distance, and generally whenever the disease is of very long duration, excision should only be undertaken as an exploratory measure, and everything should be in readiness for amputation, if the softened condition of the bones should render the latter operation necessary; as will very probably be the case, even if no part should be found absolutely carious or necrosed. In deformity the result of old disease, if the disease have entirely subsided, orthopædic measures will most probably succeed; but if the case appears beyond their reach, no grave operation ought to be undertaken, except at the express instance of the patient; or, if a child, of his parents. The operation itself has its own peculiar difficulties and dangers in such cases; but, as a general rule, *operations de complaisance*, as the French call them, should never be pressed on the patient. Excision for injury, or primary excision, is very rarely required, or justified, in civil practice;[1] and in military practice (as stated in the essay on GUNSHOT WOUNDS) it is rarely feasible. The little evidence that we possess at present appears to show that the risk is greater than that of primary amputation. Primary excision ought not to be undertaken except in young subjects, and not in them except in those rare cases where, along with an amount of injury to the joint which renders preservation of the limb without operation hopeless, there is at the same time no such extensive wound, and no such injuries to the main vessels, as to necessitate amputation, and even in these rare cases it will be always doubtful whether the injury to the bones is limited to the neighborhood of the wound, and therefore the operation is always to be regarded as an exploratory proceeding, which may terminate in amputation.

The conclusion from all this appears to be, that the cases suitable for excision are those of incurable injury or disease of the knee, in which all the circumstances, both constitutional and local, are most favorable; in which the patient is in the prime of life, and free from visceral disease; and in which there is reason for hoping that the lesion has not spread beyond the epiphyseal ends of the bone.

The operation is thus performed: an incision should be made from the back part of one condyle to the back part of the other, passing across the front of the limb below the patella, and slightly convex downwards. It is seldom necessary to make any other incision into the skin;[1] but if there is much thickening about the soft parts, perpendicular incisions may be made at the ends of this so as to form the H-shaped incision, which used always to be employed in this operation. The ligamentum patellæ is to be divided in the first incision; then the soft parts are to be thrown back from the patella and the end of the femur, and the patella is to be removed.[1] The joint is now to be freely

---

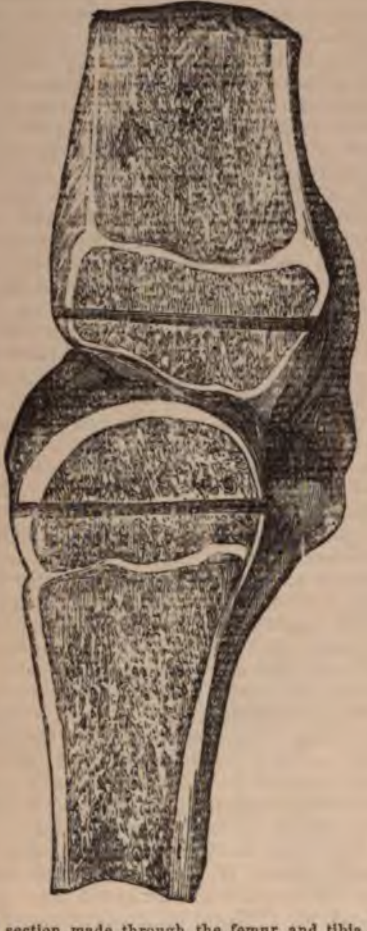
[1] I am informed by Mr. Henry Smith that in more than one fatal case at King's College Hospital death has been attributed to the shock of the operation.

[2] Speaking generally, and with due allowance for exceptional cases, I mean in persons above the age of forty-five.

[3] I do not mean to proscribe the operation in early childhood; in fact, I have often operated on very young children; but I regard the best age for this operation to be about puberty.

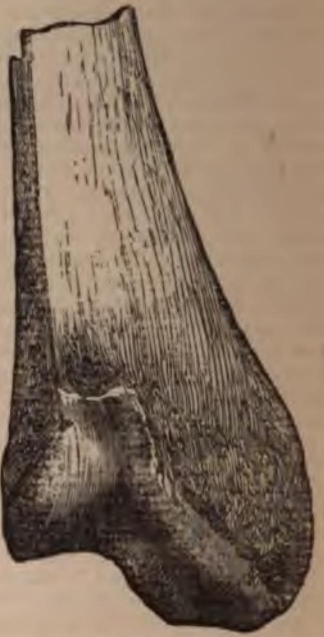
[1] Mr. Canton has published two cases in which he performed excision of the knee for injury; or perhaps, more strictly speaking, for abscess following injury.

Fig. 641.



A section made through the femur and tibia in a child aged five years, to show the position of the epiphysial lines and the point at which the section ought to be made in excision. If the section be made above the trochlear surface of the femur, at the level of the dotted line, the whole epiphysis will be removed. In the tibia, the whole articular surface may be removed without risk.

Fig. 642.



The same femur, shown in an anterior view, to mark the level at which the saw ought to be applied.

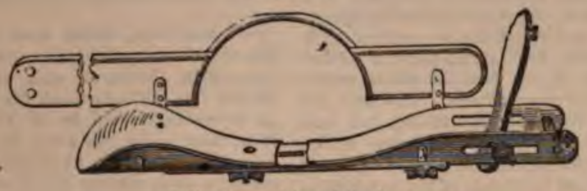
---

[1] Some surgeons prefer to make a long elliptical flap from the front of the limb, including the patella. I myself do not ordinarily use this method, as it makes a larger wound, and renders it somewhat more difficult to deal with the patella. It may, however, be necessary when there is much swelling.

[1] It is my invariable rule to remove the patella, and this is, I believe, the usual practice. I can see no use in the bone if left, and much risk of recurrence of disease. (See also Swaim, On Excision of the Knee-joint, p. 73.) Dr. Patrick Heron Watson, on the other hand, counsels its preservation, when possible, for the following reasons: "(1) That its removal is unnecessary in most cases; (2) that its presence in the flap bears up the soft parts from the line of incision, and, without preventing consolidation, helps to keep them away from the cut margin of either osseous surface; (3) that its removal occasions more bleeding; and (4) that the hollow left after its removal from the centre of the long flap leaves a hollow cavity, in which matter bags, and requires a separate incision to drain it efficiently." (On Excision of the Knee, p. 75.) If the latter assertion be well founded, it constitutes to my mind an additional objection to the use of the long flap in excision, rather than an argument for the preservation of the patella. None of the other supposed inconveniences of removing the patella will be found to be of any practical importance if the operation be performed with the simple transverse incision. As to the first assertion,

opened by cutting at the sides of the condyles, so as to sever completely both lateral ligaments; and then the knife is to be carried round the posterior surface of the end of the femur, care being taken in doing this to thrust the femur out of the wound as much as possible, by an assistant forcibly flexing the limb, and to keep the edge of the knife directed towards the bone, and guided by the finger, so as to avoid the popliteal artery, which here is separated from the bone only by some fat and loose tissue; and, in sawing the bone, it may be advisable, if the femur have not been very completely cleaned, not to pass the saw entirely through the osseous tissue, but rather to break than to cut the outer lamella at the back, by using the saw as a lever. The level at which the femur is to be divided should be carefully borne in mind in operating on children. I have repeatedly seen the surgeon take away the whole epiphysis and a part of the shaft from mere want of care, having forgotten, or omitted to ascertain, whereabouts this line is situated. Figs. 641–642 show its true position, and will prove that in any case of excision in which the whole cartilaginous surface of the femur is removed, the shaft will be trenched upon. The end of the femur having been removed, the head of the tibia is to be cleaned and sawn horizontally, care being taken in young persons to keep close below the cartilaginous surface, so that the epiphyseal line be not interfered with. In cases where there has been no dislocation, nor much alteration in the shape of the bones from previous disease, there is now usually no impediment to placing the limb in a straight position, with the bones in accurate adjustment. Otherwise they must be adjusted by taking off successive pieces from the end of the femur or tibia (if possible without going beyond the epiphysis); and in cases of old dislocation it is often necessary to sever some of the hamstring tendons. The parts should, in all cases, be adjusted in perfect position upon a splint, and the bandages firmly applied before the patient is moved or allowed to recover from the chloroform. If the femur appears at all prominent, a short splint should be applied in front in order to counteract the tendency of the leg to gravitate backwards (which is also assisted by the action of the flexor tendons); and it is at any rate a useful precaution to apply a long side-splint to the outer side of the limb, which can be discarded after the first few days, if it appears superfluous. I have found much comfort to the patient from suspending the whole apparatus in a "Salter's swing." It will of course be understood that the splints are interrupted and bracketed with iron at the seat of operation, so as to give access to the wound.

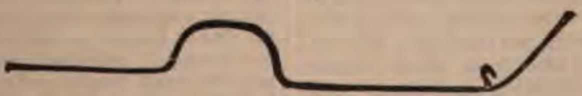
Fig. 643.



Splint for excision of the knee.

There are many other methods of dressing the wound and limb in cases of excision of the knee. Dr. Patrick Heron Watson warmly recommends the use of plaster of Paris (or plaster coated with paraffine externally, to render it less permeable to discharges), which he thus applies. Fig. 644 represents an iron rod, which extends from the groin to the foot, the upper straight end being at the groin, the arch at the site of the wound, the hook (for swinging the limb) near the ankle-joint, and the raised part running along the dorsum of the foot. Fig. 645

Fig. 644.



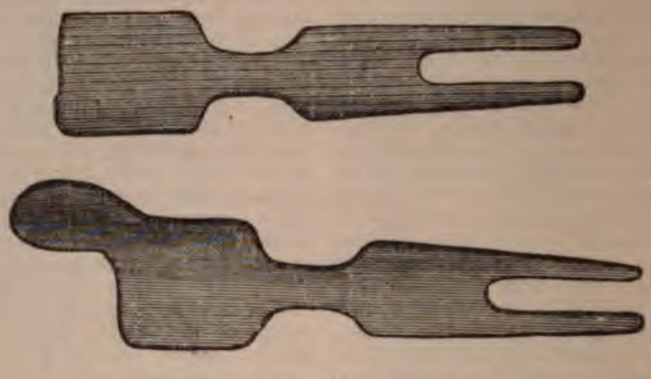
Dr. P. H. Watson's suspension-rod for excision of the knee.

---

it is a matter of experience. In my own practice, the removal of the patella has seemed in the great majority of cases not merely advisable, but necessary.

shows two forms of "Gooch" splint, the former merely hollowed out on each side at the level of the wound and cut out at the lower part in a horse-shoe or stirrup form, to relieve the heel and tendo Achillis from pressure; the latter having also a piece above to be adapted to the innominate bone.

Fig. 645.



Dr. P. H. Watson's splints for excision of the knee.

"In application, the limb is first laid and carefully adjusted upon the posterior splint, which should preliminarily be padded with lint, and covered with gutta-percha tissue, or hot paraffine, in the position which corresponds to the site of operation. The iron rod is then placed in front, and folded lint laid between it and the limb at the groin, at the upper part of the tibia, and at the bend of the ankle. These two parts of the apparatus are then retained in contact with the limb by means of an *open wove* roller bandage applied from the toes upwards, the site of the incision being alone left uncovered. The whole is then rendered immovable by means either of plaster of Paris applied by the hand, of the consistence of thick cream, or of paraffine, which, having been rendered temporarily liquid by heat, is applied by a large painter's brush. When the application has solidified, the patient may be removed to bed, and the limb suspended from the running pulley of a Salter's swinging cradle, or from the roof-bar of the common iron-wire cradle." (Op. cit., p. 19.)

The advantages claimed for this method are the comfort the patient derives from being able to shift his position; the ease of transporting him from place to place (a great consideration in military practice); the facility of applying dressings to the wound; the permanence, simplicity, and facility of construction of the apparatus itself. My own experience of this treatment is limited to two cases, but these were sufficient to convince me of the reality of its advantages. The plaster-of-Paris dressing is in general use in this and other excisions by the German surgeons.[1]

Mr. Butcher has recommended[1] a "box-splint" for the after-treatment of this operation. This consists of two side-splints, the outer one extending from the axilla to below the foot, the inner from the groin to below the foot, jointed on to a back piece. The sides are let down to dress the wound. This is, as far as I have seen, a convenient apparatus when all goes well, but is less handy when complications occur, and is, on the whole, I think, inferior to the above-mentioned methods of treatment.

---

[1] "Als wir hier mit diesem Verbande für Kniegelenksresectionen unsere ersten Versuche machten, zeigte sich derselbe so ausserordentlich praktisch und einfach, dass Herr Prof. Esmarch sich sofort veranlässt fühlte, das Princip auch für andere Gelenke zu verwerthen, und ist in Folge dessen dasselbe hier nicht nur auch für Fuss- und Ellbogen-Gelenk zur Anwendung gekommen, sondern auch mit bis dahin sehr befriedigendem Erfolg für eine Hüftgelenksresection.

"Die Patienten liegen, an welchem Gelenk auch die Resection ausgeführt ist, ausserordentlich bequem, können vom ersten Tage an ohne Beschwerde jede Stellung einnehmen, und was uns noch besonders vortheilhaft erschienen ist, wir haben in allen Fällen. . . die Nachbehandelung ohne Verband zur Anwendung gebracht. Ich glaube wenigstens, das man nur diesem Umstande es zuzuschreiben hat, das man eine Kniegelenksresection von Anfang bis zu Ende behandeln kann, ohne jemals durch eine Spur von Geruch belästigt zu werden; ja, ich glaube sogar, das man das auf keine andere Weise erreichen könnte. Dabei ist der Verband und das Glied fast beständig rein, weil der Eiter aus der Wunde hervorgedrungen, über das Glied und die durch Firniss vor Imbibition geschützte Schiene sofort herablauft und in das untergesetzte Gefäss tropft."—From Dr. Zerssen's Graduation Thesis at the University of Kiel, in 1868. I may, however, add that even more rapid cures and more complete absence of foul odor or profuse suppuration have been attained by the method introduced into practice by Professor Lister (see infra, in the essay on AMPUTATION). My colleague, Mr. Pick, treated a case of excision of the knee, in a child, by this method recently, in which the whole wound healed in a fortnight. The two methods may of course be combined.

[1] Operative and Conservative Surgery, p. 142.

[Figs. 646 and 647 show two forms of splint which have been extensively used in this country in cases of excision of the knee, and have proved very satisfactory.

[Fig. 646.

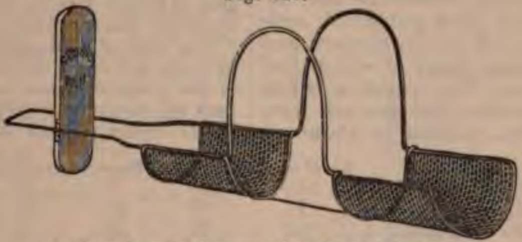
Fig. 648.



Ashhurst's splint for cases of excision of the knee.]

It is an essential element in the success of this operation not to be forced to disturb the limb at all for several days; hence the dressings should be most carefully applied at first. And for the same reason all bleeding vessels should be carefully secured, so as to avoid secondary hemorrhage. The bleeding during the operation is often very free, from the enlarged articular vessels; and secondary hemorrhage is by no means rare, and is a very unfavorable occurrence. The operation, especially when it has been a protracted one, which in cases of old dislocations it often is, is usually followed by a considerable amount of fever, subsiding with the establishment of a free suppuration; and then, in favorable cases, the work of repair commences by granulation and osseous union, as in compound fracture. In unfavorable cases, the bones become denuded and ulcerated in the suppurating cavity, the discharge is offensive, the wound unhealthy, fresh abscesses probably form, and the patient's health, instead of improving from the removal of the disease, shows a tendency to decline. Under these circumstances, chloroform [or ether] should be administered and amputation performed, if on examination it proves necessary.

The process of recovery is usually a slow one. In Dr. Hodges's tables, already referred to, the duration of the treatment in 48 cases in which the patella was removed is stated to have been 225 days; and in 38 cases in which that bone is believed to have been left, 255 days; or, roughly speaking, the average duration of treatment was about eight months; and in many of the cases which afterwards turn out the most successful, sinuses remain open, and the limb is in a state which cannot but cause anxiety for many months after formal treatment is discontinued.[1] In some exceptional cases, indeed, matters go on much more rapidly than this, and the recovery is completed as soon as (indeed, it may be that one or two have recovered sooner than) after amputation; but, as a general rule, the time required for recovery after excision may be taken at about four times as long as after amputation. In fact, I think we are taking a view very favorable to excision, if we say, that every month after the operation advances the cure only as far as a week would after amputation.

What is the value of the limb which is obtained by this operation, at the cost of such increased risk and so much additional suffering? Unfortunately, this is a question, the answer to which has been so distorted by the rash and exaggerated statements of the indiscriminate advocates of the operation, that no impartial person can profess to be able to solve it. I have seen, in many cases, most excellent limbs left after excision; far superior both for appearance and utility to any apparatus which could be manufactured after amputation, and still more to the ordinary wooden leg: and it is on account of the occurrence of such cases that I believe excision ought to be practised upon the most favorable cases of disease of the knee; but I utterly disbelieve the accounts which have been published, resting upon statements in newspapers and periodicals, of cases, many of which had not recovered from the operation, while in a great proportion the sinuses were still open, and the patient in about an equal chance of saving his limb or losing it. No case is be accepted as a successful one of excision of the knee, without *precise* information as to the following facts: Whether the wounds were all closed; whether the union was so firm as no longer to permit any motion; whether the patient could walk, and, if so, with or without apparatus; and what were the respective measurements of the limbs. It is true, that to have waited long enough to satisfy these queries would have somewhat delayed the appearance before the world of some brilliant cases, and perhaps have condemned many of them to perpetual obscurity; but, on the other hand, it would have made the information, when it did appear, useful and trustworthy, instead of, as at present, either useless or deceptive.

As far as Dr. Hodges could discover, from the data furnished by published accounts, out of 208 cases of excision, 102 failed utterly, as proved by death or amputation; and of the remaining 106, there was reason for thinking that in 65 cases the limb was useful, and in 14 partially or entirely useless; 27 being left quite doubtful; but from the nature of such accounts this conclusion cannot be a very confident one. Out of 19 cases occurring at St. Thomas's and St. George's Hospitals together, of which I have trustworthy and sufficient details, the limb was useful in 10 cases; but 9 of these were children.

The results of English practice, as far as he could ascertain them, from the invention of the operation down to a very recent period (not expressly specified) are thus tabulated by Mr. Swain in 1869:—

	No. of cases	Recoveries	Deaths	Amputations	Recoveries	Deaths
Recorded in Price's book up to 1865	316	240	76	39	30	9
Collected by Mr. MacCormac . .	74	49	25	11	7	4
Tabulated by Mr. Swain himself .	82	67	15	4	4	0
	472	356	116	54	41	13

Thus we have 472 cases, with a mortality of 116 = 24.57 per cent. Of the 356 who recovered from the immediate effects of the operation, 54 underwent subsequent amputation (13 of them dying), leaving 302 with useful limbs.[2]

I give this table as Mr. Swain gives it, and cordially agree with him in his low estimate of the value of such statistical information. Such tables can in fact prove very little. They do indeed show that the mortality has diminished: but whether this has arisen from improved surgery—that is, from a better style of operating and after-treatment—or from a more indiscriminate application of the operation to cases of slighter disease which need not have been operated on at all, but in which the patients will of course be more likely to survive operation (and which I would call deteriorated surgery), neither is nor can be shown by statistics. It is also a somewhat suspicious feature in Mr. Swain's table that all the 302 recoveries are claimed as being with useful limbs. If the information had been at all adequately full, there would surely have been a category of recoveries with the limb more or less useless.

Another very serious consideration in cases which recover with useful limbs is, whether that usefulness will be permanent. It is now a well-known fact, that the utility of the limb in many cases in which it seemed perfect at first has been destroyed by subsequent changes. In adults, the union, although it has appeared quite firm, sometimes proves not to have been so, and the limb bends under constant use, and yields to the power of the flexor muscles, until the foot no longer touches the ground, and the whole extremity becomes an incumbrance instead of a support. Sometimes it bows outwards or inwards, but with the same general result. Occasionally disease recurs, after a shorter or longer interval of apparent health, either spontaneously or as a consequence of some accidental injury or over-exertion.

---

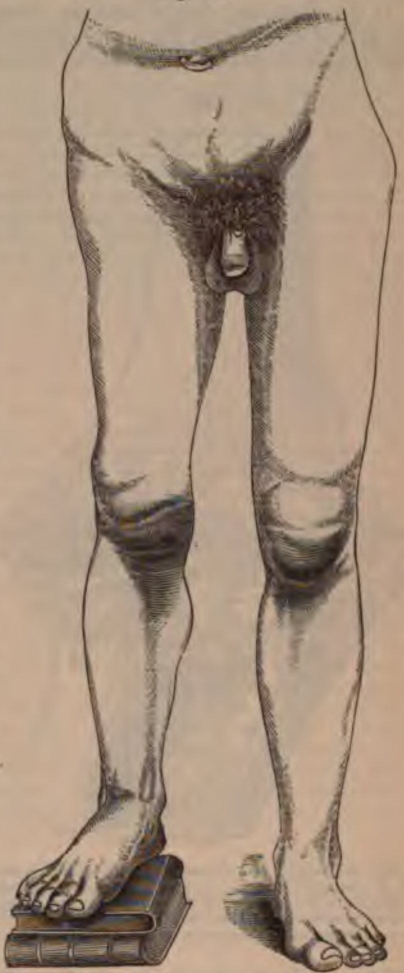
[1] In a series of eight successful cases, all of them in children, at St. Thomas's Hospital, for the notes of which I am indebted to Mr. Allingham, the average duration of treatment was 206 days. From the notes of 50 successful amputations of the thigh, at St. George's Hospital, I find that the average stay in hospital was 53 days. This includes patients of all ages. Children and young persons, such as are alone the subjects of excision, recover from amputation more rapidly than the average.

[2] Swain, op. cit., p. 64.

Suspension of growth after excision of the knee in childhood is very liable to occur; and is usually caused by removal of the entire epiphysis,[1] with encroachment on the shaft of the femur, and possibly of the tibia also. I have already spoken of the precautions which ought to be taken in operating on children to avoid this, and I believe that in most cases the disease can be entirely removed and the epiphyseal line left intact. But allowing that shortening occurs even to a very great extent, the limb may nevertheless be very useful. For a proof of this I would refer the reader to various cases published by myself and others, which have been quoted by Mr. Swain,[2] and for the details of which I have not space here, and to some admirable remarks by Sir W. Fergusson in the sixth of his lectures On the Progress of Anatomy and Surgery, illustrating the value in these cases of the preservation of the healthy leg and foot.

I recently saw a case in which I had operated eight years before, and where I had been obliged to remove the femur higher than the epiphyseal line,[3] and in whom therefore there had been progressive shortening. The patient has now attained the age of twenty-two; his growth appears complete; all irritation in the site of the wound has long since disappeared; the shortening now reaches six and a half inches; it is compensated partly by a dropping of that side of the pelvis to the extent of about two inches; the heel of his boot measures four inches in height; he walks with a slight limp, can walk any distance, and at the rate of over four miles an hour, and has done twenty-five miles in a day without fatigue. The muscles of the thigh on the side operated on are much wasted.

Fig. 649.



Result of successful excision of the knee. (From a photograph.) To show the dropping of the pelvis on the affected side, by which the shortening is partly compensated, and the atrophy of the muscles of the thigh which follows on disuse of the knee-joint, while those of the leg are little affected.

The repair after excision of the knee may be illustrated by reference to the preparation figured on p. 230. It is true that this was not a completely successful case; but repair was very far advanced, and had it not been for the visceral disease, it would, I doubt not, have been completed. As the case was under my own care, I may add that it serves also as an "exemplar ad evitandum," showing the deformity which is sometimes, in spite of all ordinary care, introduced into the union by displacement of the bones of the leg, and which both renders the limb less straight and comely, and doubtless tends to weakness in the union and subsequent displacement.

---

[1] Suspension of growth has, however, been noticed in one case at least, under Mr. Syme's care, where the epiphyseal lines appear to have been left intact.

[2] Op. cit., pp. 141 to 148.

[3] Surgical Treatment of Children's Diseases, 2d ed., p. 486.

If the limb be simply bent in consequence of soft union, the only treatment required is to straighten it under chloroform, and keep it straight in a carefully fitted splint for some months, with due attention to the general health, the patient being put in good pure air, and allowed to take moderate exercise upon crutches. When disease is present in the bones, it becomes a question whether the diseased bone can be removed, or whether the limb should be amputated. Some surgeons have even proposed the complete re-excision of the false joint by an operation similar to the original one—a proposition highly worthy of consideration if the patient has attained his full growth and is in good health, and the shortening left by the first operation is not great. Such re-excision must, however, always be proposed to the patient as an exploratory operation, which in many cases will have to terminate in amputation.

Fig. 650.

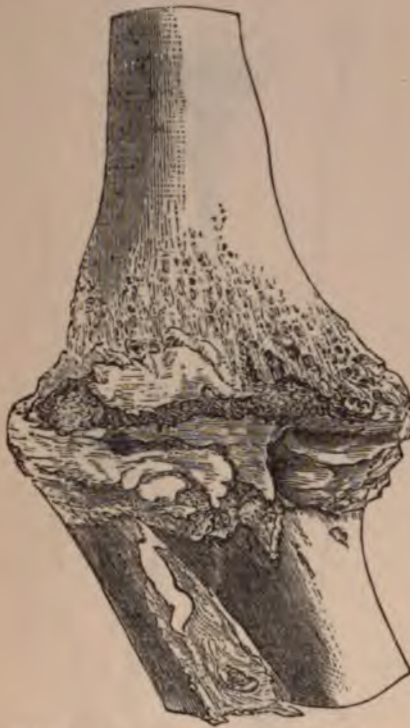


Fig. 651.

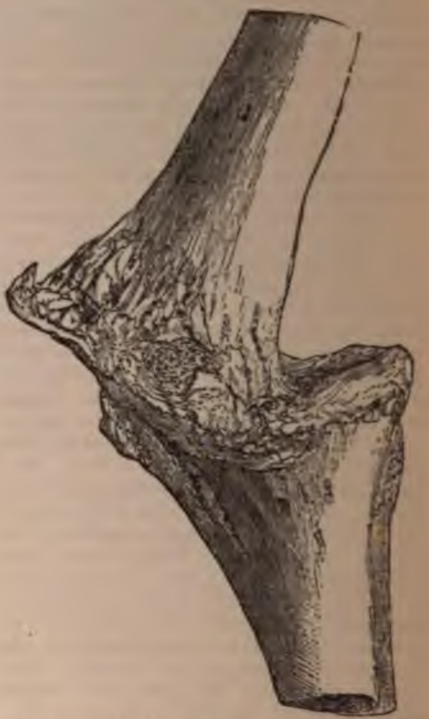


Two views of a preparation, showing almost complete repair after excision of the knee. (From the Museum of St. George's Hospital.) Fig. 650 shows the uniting medium almost perfect, but slight carious disease still going on in the bone. Fig. 651 shows the tilting backwards of the bones of the leg, or "riding of the femur," which is so liable to occur after this operation. The patient, a girl about the age of puberty, had nearly recovered from the operation when signs of renal disease showed themselves, and she gradually sank.

Excision of the ankle.—In the first edition of this essay I spoke discouragingly of the operation of excision of the ankle, not having at that time had any personal experience of the operation in my own practice, though I had seen many cases under the treatment of others, and those very eminent surgeons. My individual experience is still very limited (in fact, the operation is one which is rarely indicated), but it has been very satisfactory, being confined to two cases which recovered rapidly, and, as I believe, completely. The operation is one on which a wide difference of opinion prevails. There are many surgeons who have never practised or witnessed the operation, many who are entirely opposed to it on principle, believing amputation at the ankle-joint preferable; others who, after a limited and unsatisfactory experience of it, have abandoned it; and, lastly, others who, like myself, believe that it is very advisable and advantageous in appropriate cases, but believe, also, that those cases are rare. The cases to which I allude are those in which the disease is of traumatic origin, and the patient in the vigor of life, unaffected by any constitutional malady. In such cases the inflammatory softening, or suppuration, does not usually extend far from the neighborhood of the joint originally implicated, and after the removal of the diseased bone, the parts take on a healthy action, and become rapidly consolidated. In strumous disease, on the other hand, inflammatory softening, if not diffused suppuration, often exists in the tarsal bones or the bones of the leg, in parts not exposed to view in the operation; and in patients laboring under general constitutional affections, the parts operated on, instead of consolidating, usually soften, and after a long and exhaustive suppuration, the bones are found carious, leaving no resource except amputation, and that under very unfavorable circumstances. Again, as to the extent of the local disease. A case, to be strictly a favorable one for excision of the ankle, ought to be one in which the lesion is limited to the epiphyseal ends of the bones of the leg on the one side, and to the astragalus on the other.[1] Still, cases are on record in which most extensive excisions, involving the ankle-joint, and more or less of the tarsus, have been followed by complete success,[2] but it must always remain a question in any given case whether the prospect of complete and speedy cure by amputation ought not to outweigh the doubtful chance of preserving the mutilated foot, which after all may be of little use, even should it continue free from recurrence of disease.

With respect to excision of the ankle for injury, I need say little as to the use of the operation in military surgery, since the question has been elsewhere treated (see the essay on GUNSHOT WOUNDS). The successful experience, however, of Langenbeck in this operation, besides its special bearing on military practice, is also important in considering the general question of the advisability of attempting resection in preference to amputation in severe and incurable injury of the ankle. M. Ollier's experience, though not so extensive, is perhaps still more to the purpose in this respect, that it is gained entirely in civil practice.

He reports (loc. supr. cit.) that he has practised resection three times for comminuted fractures of the lower ends of the bones of the leg. In one case—a man 49 years of age—about one-third in length of the tibia was removed (12 centimetres = about 4 inches). The reproduction was not complete, but the patient recovered sufficient power to carry on his trade of a cooper.—In the second case, 7 centimètres in length of both bones were removed. The patient, a midwife, was at the time of the report (length of time after the operation not stated) able to walk with a stick and to attend to her business.—In a third case, the patient died of cerebral complications produced by the same injury. A still larger portion of bone (16 centimètres) had been removed, and all was going on well as far as the operation went.—M. Ollier also refers to another case under the care of MM. Jambon and Aubert (of Mâcon) where 10 centimètres of the tibia were removed; the patient had completely recovered, could walk ten miles, and dance for hours together.

Mr. Hancock, in his lectures at the Royal College of Surgeons in 1867,[1] referred to numerous cases in civil practice in which excision of the ankle (or at least of the extremities of the bones of the leg) had been practised successfully on account of injury. Nineteen successful cases are referred to by Mr. Hancock (one of which is of peculiar interest, inasmuch as the operation was practised on both sides), and he mentions that "Heyfelder gives 26 examples of this operation, of which 5 died, and 1 suffered consecutive amputation; while Jaeger, on the other hand, records 24 cases, 23 of which proved successful, and 1 died."

In almost all cases of excision for injury, the operation has been rather a resection of the fractured ends of the tibia, fibula, or both, than a complete excision of the ankle.

These facts appear to demonstrate that in complicated injuries about the ankle, resection may be performed with good hope of success if the patient be healthy, and if the after-treatment be judicious.

We are not in a position to lay down rules for the preference of excision over the expectant treatment on the one hand, or amputation on the other. "Each case," as Mr. Holthouse says,[2] "must be studied separately, and the means adapted to the circumstances present." But I think that we may conclude, generally, that excision is preferable to amputation in young patients of healthy constitution and habits, and that it is preferable to the expectant treatment in cases of great comminution of bone associated with comparatively slight injury to the soft parts.

---

[1] M. Ollier would still further restrict the application of this excision. He says: "C'est seulement pour les ostéites épiphysaires des os de la jambe, avec propagation de l'inflammation suppurative à l'article, que je crois cette resection nettement indiquée." (Des Resections des grandes Articulations, p. 26.) Lyon, 1869.

[2] In one case referred to by Dr. Hodges, the ends of the tibia and fibula, the whole of the astragalus, part of the os calcis, and the three cuneiform bones, were removed; in another the end of the tibia, the astragalus, scaphoid, and two of the cuneiform.

[1] Lancet, vol. ii., 1867, p. 121.

[2] INJURIES OF THE LOWER EXTREMITY, Vol. I., p. 981.

With regard to the operation itself, I cannot do better than quote Mr. Barwell's description of the operation, as originally devised by Mr. Hancock, and which is, as far as I know, the best operative procedure for the removal of the entire joint; that is to say, the ends of the bones of the leg and the articular surface, or, if necessary, the whole of the astragalus. "The foot is first laid on its inside, and an incision is made over the lower three inches of the posterior edge of the fibula. When it has reached the lower end of the malleolus, it forms an angle, and runs downwards and forwards to within about half an inch of the base of the outer metatarsal bone. The angular flap is reflected forwards; the fibula, about two inches above the malleolus, is sufficiently cleared of soft parts to allow cutting forceps to be placed over it; and the bone is then nipped in two and carefully dissected out, leaving the peroneus longus and brevis tendons uncut. The foot is now to be turned over. A similar incision is made on the inner side, the portion on the foot terminating over the projection of the inner cuneiform bone. The flap is to be turned back, and the sheaths of the flexor digitorum and posterior tibial tendons exposed, the knife being kept close to the bone, avoiding the artery and nerve. The internal lateral ligament is then to be severed carefully, close to the bone; and now the foot is twisted outwards, and the astragalus and tibia will present at the inner wound. A narrow-bladed saw, put in between the tendons into the inner wound, projects through the outer. The lower end of the tibia, then the top of the astragalus, may be sawn off in a proper direction. The only vessel that may require tying is one of the lower branches of the peroneal artery. The wound may be closed with sutures, except that part opposite the breach of osseous matter; the leg and foot placed on a splint with a foot-board, and cold water applied."

Dr. M. Buchannan has also described[1] an operation for excising the ankle-joint, by making a curved incision over the external malleolus, removing this process with the bone forceps, dislocating the joint by inverting the sole of the foot, and thus obtaining access to the diseased bones without dividing any important parts, the peronei tendons being the only structures necessarily divided. This proceeding is merely a portion, as it were, of the one described by Mr. Barwell. It cannot give so free an access to the bones as is obtained by the former; but it may be adopted in cases where the end of the tibia does not require entire removal with the saw. The operation may, therefore, be commenced by making merely the incision on the outer side; and then if it be found necessary, that on the inner side may be added.

Langenbeck and Ollier have preferred the subperiosteal method of operating, and for the removal of large portions of bone in recent injuries there can be no question that this method should be preferred. In disease I think the method is of little consequence, because I do not believe that any large quantity of bone could be removed with success, unless for necrosis, when the periosteum would probably separate of itself. If only a small slice of the bones of the leg were removed, I should think it a matter of little consequence whether reproduction occurred or no. No express directions are needed for the subperiosteal operation beyond those given at p. 204.

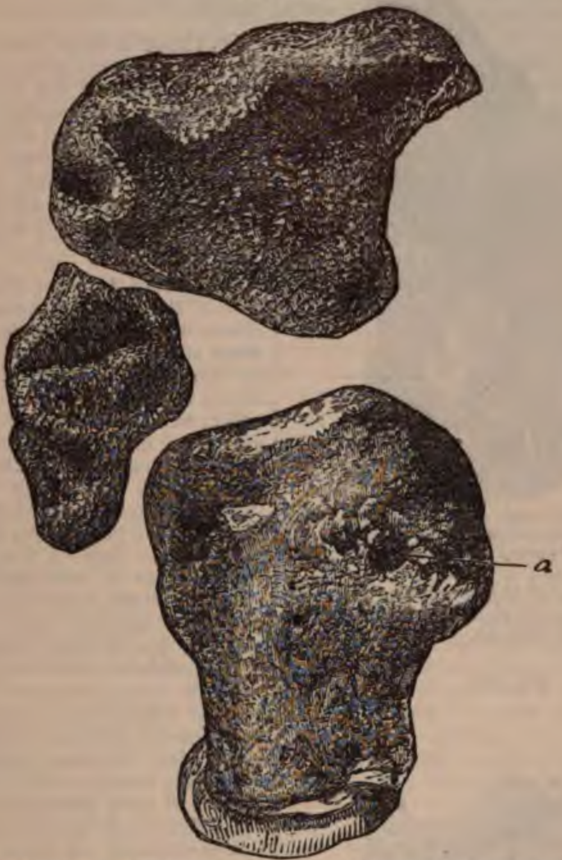
I have elsewhere[1] pointed out the advantages which are to be derived from the removal of the entire astragalus in cases where that bone is at all extensively affected. In fact, whenever the disease appears to have commenced in the astragalus, I think it is better to remove the whole bone; and still more is this the case if the sides of the bone are ulcerated and freely exposed, since in such circumstances the lower surface will also probably be found affected. Such was the case in the instance to which I refer, and from which figs. 652 and 653 are taken. They show the implication of all the articular surfaces of the astragalus, except that of its head, in the ulceration. The removal of the whole astragalus requires free incisions, and is somewhat laborious, but it affords complete access to the upper surface of the os calcis, which can be removed, if necessary, with the chisel, and even to the anterior part of the tarsus, if it should be judged necessary to deal with this. In the after-treatment, perfect rest of the foot is essential until the parts are somewhat consolidated. When this is effected, the foot may be supported on a splint, and the patient be allowed to go about, resting the knee on a wooden leg. I have hitherto treated my patients in the way which is common, in compound fracture of the leg, at St. George's Hospital, viz., by confining the foot and leg in Assalini's fracture-box, dressing the wounds at first with carbolic acid on Mr. Lister's plan, and at a later period—when suppuration has been fairly established, and the acute inflammation has subsided—with oakum. Langenbeck insists strongly on the advantages of the plaster-of-Paris splint in these cases, as in so many others, and I am informed by Dr. Patrick H. Watson that he has combined with the gypsum bandage a suspension rod similar to the one which he uses for excision of the knee (see p. 225), but without any splint. Professor Esmarch, of Kiel, has also adopted Dr. Watson's plan, and both surgeons have found the results very satisfactory.

---

[1] Glasgow Medical Journal, vol. ii., p. 1.

[1] St. George's Hospital Reports, vol. iv.

Fig. 652.



Bones removed in excision of the ankle, showing the ends of the bones of the leg and the upper surface of the astragalus.

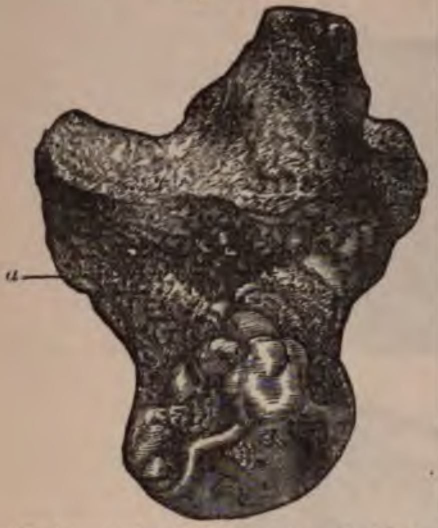
In cases of successful excision, the limb is very much superior in usefulness to any stump which can be formed, whether by Syme's or any other method of amputation.

One of these successful cases was exhibited at the Pathological Society in 1863. The excision had been performed, several years before, by Mr. Hancock. The foot was firmly ankylosed to the bones of the leg, and at a perfectly convenient angle. The shortening was but slight, and the man could walk almost as well as ever.

Fig. 654 was taken from a case in which I excised the ankle-joint in 1869. His present condition is thus reported by my friend, Dr. Nicholls, of Chelmsford, near whom he resides: "The operated leg is slightly shortened; all the wounds are healed; he walks, with the aid of a boot with irons, as much as half a mile, without inconvenience." In this instance the disease was abscess of the lower end of the tibia, bursting into the joint. Only the upper part of the astragalus was removed, that bone being quite healthy.

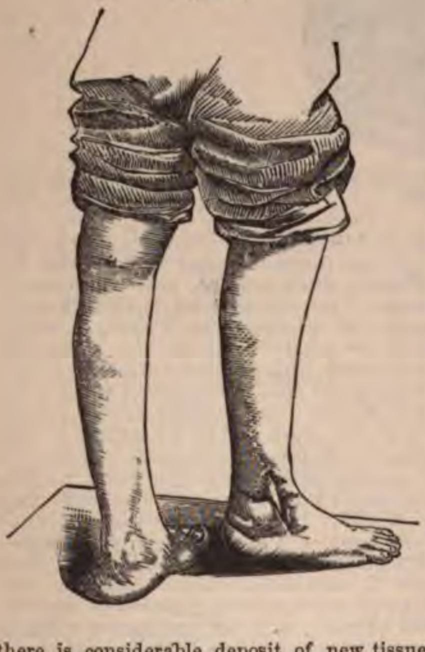
An interesting case is reported by Dr. Murney in the Dublin Quarterly Journal for February, 1870, in which the left ankle-joint had been completely excised eleven years before. The patient's state is thus described: "He is now 27 years of age, muscular and strong, has enjoyed uninterrupted good health since he left hospital; is active and fond of walking, and considers the left is stronger than the right limb; does not use a stick; in progression there is a slight halt, but no more than is frequently observed from a corn. This, to the ordinary observer, would be attributed to a slight *in-turning* of the toes of the left foot,* as when he walks the right foot is turned out, the left is placed straight. On examination, there is considerable deposit of new tissue between the bones which were cut. The foot is slightly extended. This makes the toes and anterior part almost of proper length, but the heel is 1½ in. higher than its fellow, which he remedies by placing a wedge-shaped piece of cork in the heel of his boot. The power of extension of the toes is as complete as in the opposite limb, and sensation is also perfect.

Fig. 653.



The lower surface of the astragalus. The letter *a* in this and the previous figure shows the pit made in the astragalus by the grasp of the lion-forceps.

Fig. 654.



On the other hand, cases occur in which the result appears good for the time, but the success turns out to have been only temporary; the wounds, after healing, break out again, and local, perhaps combined also with general, disease reappears. I do not know that this is more particularly the case after excision of the ankle-joint than after any other of these operations.

Excision of the bones of the foot.—In disease of the tarsal or metatarsal bones excision is often very successfully practised when the disease is limited to the os calcis behind, or to single bones of the metatarsus in front; but it is of more doubtful utility when the bones which are affected are those covered by the large common synovial membrane of the tarsus. These bones, both from their small size and from being portions of the same joint, are very liable to become involved in the same action, and thus it frequently happens that disease is only eradicated at one point to show itself some weeks afterwards at another, and the attempt to save the foot is often unsuccessful. But in favorable cases it ought to be made, since the operations involve little danger, and no confinement beyond what would be rendered necessary by the disease itself. Many surgeons prefer gouging out the whole carious cavity, leaving a shell formed of bone presumed to be healthy, and of the soft parts around; an operation sometimes dignified by the name of "subperiosteal resection," and described by M. Sédillot under the name of "évidement de l'os." The alleged advantages of this proceeding are, that the bone may be reproduced, and that the great tendons will be left in their natural attachments. I do not attribute very much importance to either of these considerations. No direct evidence, as far as I can discover, has been given that the natural bone will be reproduced after such gouging. I mean by "the natural bone," a bone which will fill up the place of the original bone, and have the same articulations; and by "direct evidence," the dissection of a foot in which this has taken place. The disadvantages are all of them summed up in the fact of the difficulty of being sure that the whole of the diseased bone has been removed. When the whole of the os calcis, of the astragalus, or of the first metatarsal bone, has been involved, except a small exterior portion of dubiously healthy bone, I have not scrupled to dissect out the entire bone without respect to the periosteum, and have seen no reason to repent having done so. The foot has been left in a very serviceable condition; and I much doubt whether the addition of a few detached pieces of bone to the cicatrix (which I believe would have been the entire result if the periosteum had been left behind) would have affected the usefulness of the foot in any way.

Excision of the os calcis is an operation which may often be practised with great advantage. Disease of the tarsus very commonly begins in the joint between the calcaneum and astragalus, and frequently spreads into the former bone; the affection of the latter being so superficial that the carious spot can be gouged away when the greater mass of disease has been removed. In these cases the central part of the calcaneum often perishes, leaving a large mass of necrosis enclosed in a thin-walled cavity of inflamed and softened bone. If now the whole bone, including this shell of softened bone, be removed, the patient makes a certain and speedy recovery with a useful foot; while if the loose portion be removed, and the shell scooped, he may, it is true, recover, and the heel may possibly be more firm, but the recovery is at least doubtful, and in the course of a tedious convalescence the health may give way, fresh disease be lighted up, and amputation become necessary.

Excision of the os calcis is thus performed: An incision is commenced at the inner edge of the tendo Achillis, and drawn horizontally forwards along the outer side of the foot, somewhat in front of the calcaneo-cuboid joint, which lies midway between the outer malleolus and the end of the fifth metatarsal bone. This incision should go down at once upon the bone, so that the tendon should be felt to snap as the incision is commenced. It should be as nearly as possible on a level with the upper border of the os calcis; a point which the surgeon can determine, if the dorsum of the foot is in a natural state, by feeling the pit in which the extensor brevis digitorum arises. Another incision is then to be drawn vertically across the sole, commencing near the anterior end of the former incision, and terminating at the outer border of the grooved, or internal, surface of the os calcis, beyond which point it should not extend, for fear of wounding the posterior tibial vessels. If more room be required, this vertical incision may be prolonged a little upwards, so as to form a +.[1] The bone being now denuded, by throwing back the flaps, the first point is to find, and lay open, the calcaneo-cuboid joint; and then the joints with the astragalus. The close connections between these two bones constitute the principal difficulty in the operation on the dead subject; but, as has been already stated, these joints will frequently be found to have been destroyed in cases of disease. The calcaneum having been separated thus from its bony connections by the free use of the knife, aided, if necessary, by the lever, lion-forceps, etc., the soft parts are next to be cleaned off its inner side with care, in order to avoid the vessels, and the bone will then come away. The flaps are to be closed lightly, with one or two points of wire-suture, over the large gap left by the excision.

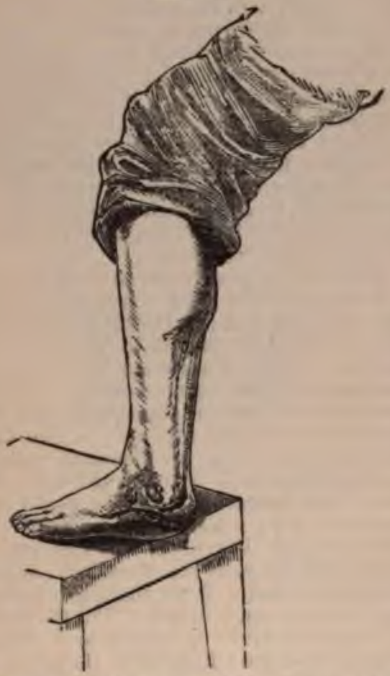
This plan appears more convenient and less bloody than that recommended by Mr. Hancock and Mr. Guthrie, of making a flap from the heel and throwing it up, as done in Syme's amputation. Even if the diagnosis has been erroneous; if disease should become apparent in the astragalus or in the fore-part of the tarsus, when the bones are denuded, and so the surgeon should be led to amputate the foot, that operation could be easily accomplished by a slight extension of the incisions just described. In this way I have often removed the os calcis in a very short time, and without finding it necessary to tie a single artery. The filling up of so large a cavity is of course a rather tedious business: in most of the cases of which I have notes, recovery was not completed in less than three months; and probably the patient does not recover the power of putting the foot to the ground for another month or more. But when it is soundly healed, the foot is a very useful one; and I have seen children who could run, dance, etc., pretty nearly as well as with the natural foot.

M. Ollier describes an operation by which the os calcis can be removed subperiosteally without the division of any tendons, except the tendo Achillis. An angular flap is made by an incision running horizontally along the lower outer border of the bone, and vertically along the outer border of the tendo Achillis. Then the periosteum and the parts above it, including the peronei tendons, are peeled off the bone. Next the attachment of the tendo Achillis and the periosteum are detached from the tuberosity of the os calcis. Then the joints are opened, and the inside of the bone is cleaned, and so its removal is completed. I have only practised this operation on the dead subject. It seems to me feasible enough, and worthy of trial; but my experience of the ordinary operation has been so favorable, that I have been the less anxious to adopt this modification.

---

[1] I have always divided the tendons of the peroneus longus and brevis. They can, of course, be dissected out and held aside with a blunt hook, but I have not observed any bad effects from their division.

Fig. 655.



Drawing from the photograph of a patient in whom the os calcis, almost the whole astragalus, and a portion of the scaphoid bone, had been removed by Dr. Nicholls.

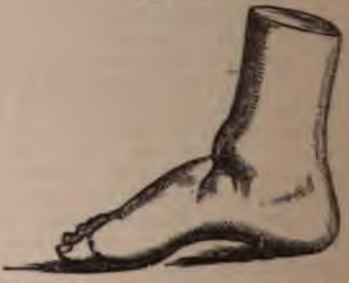
After recovery, the only mark of deformity in the foot is an elevation of the heel proportionate to the size of the bone removed. This can be judged of by fig. 655.

Even when the astragalus is also diseased, the foot may be perfectly useful after the removal of both the diseased bones. Thus at the Medico-Chirurgical Society of Edinburgh, December, 1869, Dr. Watson showed a cast taken recently from the foot of a boy on whom he performed excision of the astragalus and os calcis, in July. The cast showed how a dense mass of tissue occupied the gap resulting from the operation. The posterior portion of the arch of the foot being gone, of course the patient could not expect to retain the spring of the foot; but in spite of this, not only was walking easily effected, but the foot, as was seen, presented a most seemly appearance.[1]

A somewhat similar case occurred in the practice of Dr. Nicholls, of Chelmsford, the os calcis, almost the whole astragalus, and a portion of the scaphoid, having been removed in two operations. The patient can walk quite well and with a hardly perceptible limp; the appearance of the foot is shown in fig. 655.

Excision of the Astragalus.—The astragalus is easily removed by making a curved incision from one malleolus to the other, something like that made at the beginning of Syme's amputation. The ankle-joint is then to be laid freely open, and the whole upper part of the diseased bone thus exposed. Then the ligaments connecting it to the scaphoid are to be severed, and the bone is to be levered up, when the interosseous ligament connecting it with the os calcis will, if entire, be felt, and can be readily divided. All that is then necessary to complete the operation is to clean the back part of the bone, which should be done with care, in order to avoid injury to the tendons and vessels which lie near it. I have had several cases in children, and have seen one in an adult, in whom a very useful foot was left; one of these is represented above.

Fig. 656.



The foot after recovery from excision of the astragalus. In this case the scaphoid bone, which had become ankylosed to the astragalus, was also removed.

[Fig. 657.

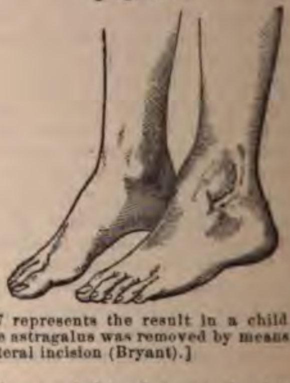


Fig. 657 represents the result in a child æt. 6, in whom the astragalus was removed by means of an external lateral incision (Bryant).]

The bone might, also, no doubt, be removed by two lateral incisions similar to those used in excision of the ankle. This would avoid the injury to the tendons and vessels incidental to the above method; but would be more laborious.

---

[1] Edin. Med. Journ., Jan., 1870.

No formal directions are required for excising the other tarsal bones. The soft parts are to be thrown aside by crucial incisions, radiating from the sinuses which lead to the diseased bone, and the latter removed; care being taken in all cases where it is possible, to excise the whole bone with the articulating surfaces.

The metatarsal bone of the great toe is very often diseased; and from its large size the disease may go on in its substance for a long period without affecting any other bone. In such cases, after a sufficiently patient trial of the appropriate constitutional treatment, with rest, it is proper to expose the disease; and if this is found to include the greater part of the bone, then the best course is to remove the whole, with both its articular surfaces. This may be readily done by making an incision over the whole length of the bone, joined by shorter perpendicular cuts in front and behind, and thus turning back small rectangular flaps including the whole length of the bone. It is better to commence by severing it from the cuneiform bone, as in dividing it from the phalanx the plantar arch will most likely be wounded, and the bleeding may prove somewhat embarrassing; whereas if the artery be not divided till the bone is removed, there is no difficulty in tying it. No splint is required. The great toe sinks down somewhat towards the tarsus, but the foot is as useful in progression as before.

Should single metatarsal bones in the centre of the foot be diseased, it is better to gouge away the whole of the diseased part; or if the affection seems too extensive, to amputate the toe, and dissect out the metatarsal bone from the posterior end of the wound.

The above are all the operations of excision which it seems necessary to describe particularly. Dr. Humphry has removed the condyle of the jaw (see DISEASES OF JOINTS); and the same surgeon on one occasion excised a fractured portion of the patella; but the superficial position of these bones, and the rarity of the operations, render any formal description superfluous.

The operations on the upper and lower jaw have been described in connection with the surgery of that part of the body.

Total or partial resections of long bones.—When the entire thickness of a long bone is diseased, it may sometimes be advantageous to remove the diseased portion only. In this way portions of the ribs have been resected on account of caries, probably in order to avert the occurrence of pleuritic inflammation from the neighborhood of the diseased bone; an operation of some risk and very doubtful utility. Or portions of the shafts of the ulna, radius, tibia, or fibula, have been cut out, with a view of promoting the healing of ulcers that seemed otherwise incurable, or getting rid of an obstinate affection of the bone. Many operations for necrosis are also erroneously entitled resections of the bones, when they are really only extractions of sequestra; but in a few cases the necrosed shaft has been removed while yet connected to the living bone. Such operations, however, whether undertaken on account of caries or necrosis, too often result in failure. In cases of necrosis of a portion of the thickness of a bone, resection should very rarely be practised—perhaps we might say never, unless for the relief of inflammatory symptoms propagated from the diseased bone to neighboring organs. Nor, in cases of necrosis of the whole thickness of the shaft, is it usually advisable to operate until the old shaft has separated from the new bone. No special directions are needed for these operations. The chief point to be attended to is to keep as close to the bone as possible, in order to spare not merely the tendons, vessels, etc., which may lie in relation with the diseased bone, but also the periosteum; so that there may be as good a prospect as possible of the regeneration of the part removed.

Subperiosteal excision of the shafts of long bones.—In cases of diffuse periosteal abscess, it will occasionally happen that the whole thickness of the shaft of the bone perishes, and becomes separate, or separable with very trifling force, from the adjoining bone, whether at the epiphyseal lines, or at some part of the continuity of the diaphysis. In such cases the old practice was either to amputate, or to persevere in the expectant treatment until a sufficient periosteal deposit of bone had formed to restore the integrity of the shaft and support the muscular movements. I have in another essay[1] expressed my conviction that the latter plan of treatment should be abandoned, and that it is better, speaking generally, to remove a dead piece of bone whenever it is possible, without waiting for osseous reproduction. There are also cases, as I believe, where the subperiosteal resection of the whole shafts, or of large portions of the whole thickness of the shafts of the long bones, will much improve the patient's prospects of recovery, and in all probability obviate the necessity of amputation.

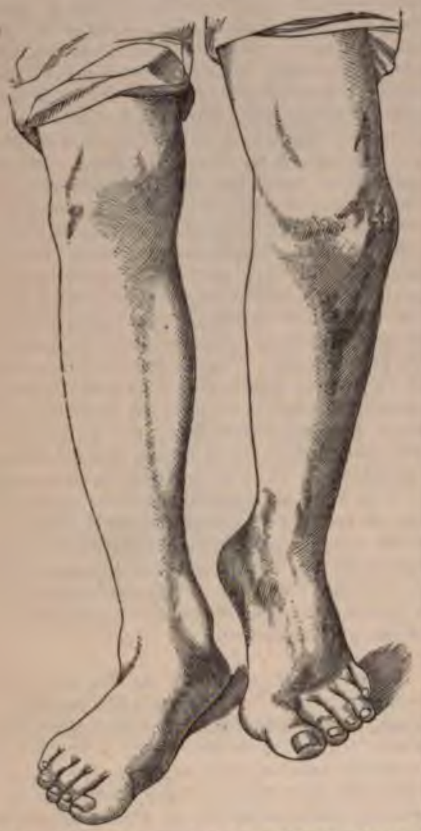
[1] DISEASES OF THE BONES, p. 156.

Fig. 658.



From a boy in whom the whole of the diaphysis of the tibia had been removed. To show the shape of the limb after reproduction of the bone, and the extent of the resulting shortening.

Many striking cases illustrative of the advantages of this operation have now been put on record. I may refer to a case of a boy, aged 10, in which I removed the whole diaphysis of the tibia, which had separated from both its epiphyses, one month after the commencement of acute periostitis; to another in which I removed a portion, 3½ inches in length, of the shaft of the femur about four months after the commencement of the disease, and before any periosteal bone had formed;[1] to another in which Mr. Joseph Bell, of Edinburgh, resected a still larger portion of the femur;[2] to a striking case by Dr. Cheever[3] of Boston, U. S., of resection not only of the whole diaphysis, but also of the lower epiphysis of the tibia, at the age of 13, where nine inches of bone were removed, the ligaments of the ankle-joint divided, and the articular end of the tibia formally dissected away from the fibula and astragalus, good motion resulting; and, finally, to three cases which may be found in M. Ollier's work, above referred to, under the care of Letenneur, Larghi, and Crus y Manso, in which the whole diaphysis of the tibia was successfully removed.

In all these cases, in which the whole thickness of the bone is removed for any considerable length, it appears to me, as far as I can discover, that shortening always ensues when the bone is solitary, as the femur; and almost, if not quite always, when it is the chief bone of the limb, as the tibia. The head of the fibula in these cases experiences a gradual displacement upwards. When it is the subordinate bone, as the fibula, or of equal rank, as one of the bones of the forearm, the other bone prevents the necessary approximation of the parts under muscular contraction, and the reproduced portions of the bone do not unite. Such, at least, has been my experience, but the cases are as yet too few to justify any confident general statement.

The operation is usually one of extreme facility. A very free incision should be made along the superficial aspect of the bone, and the periosteum separated by means of the handle of the scalpel, or other blunt instrument. This being done, a chain-saw is to be passed under the bone, and its divided ends seized with the lion-forceps and gently twisted. If they will come away from the epiphyseal lines, the operation is over; otherwise the chain-saw must be again applied at the limits of the separated periosteum. If the articular end is also to be removed, its ligaments must of course be divided. It is far more satisfactory to find the separation of the dead bone already complete, than to have to make the division of the dead bone from the living with the saw, though cases are on record in which the latter proceeding has proved successful.

Space hardly allows of a proper discussion as to the propriety of such operations as these under different circumstances. In all the instances referred to the operation succeeded. In one, in which I removed a portion only of the shaft of the tibia, it failed, and amputation became necessary, the patient recovering. But the cases have been far too few at present to enable us to judge as to the relative safety of this course and amputation. All that I will say here on the subject is, that in early life (and most, if not all, these cases occur in childhood), when the whole thickness of the shaft of the bone perishes in consequence of acute periosteal abscess, and is separable from the neighboring portions, subperiosteal exci-

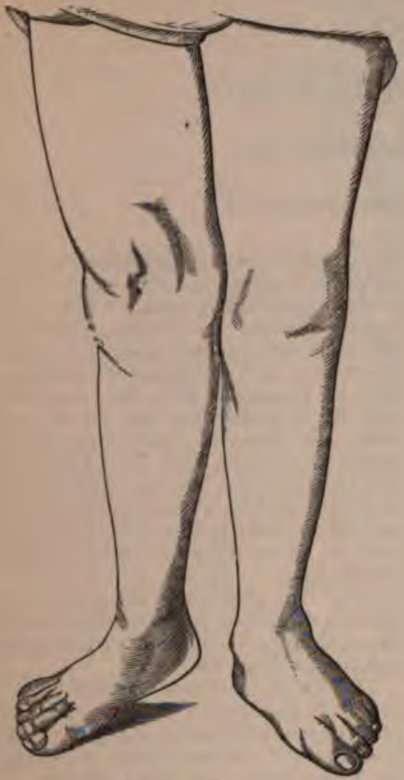

Fig. 660.

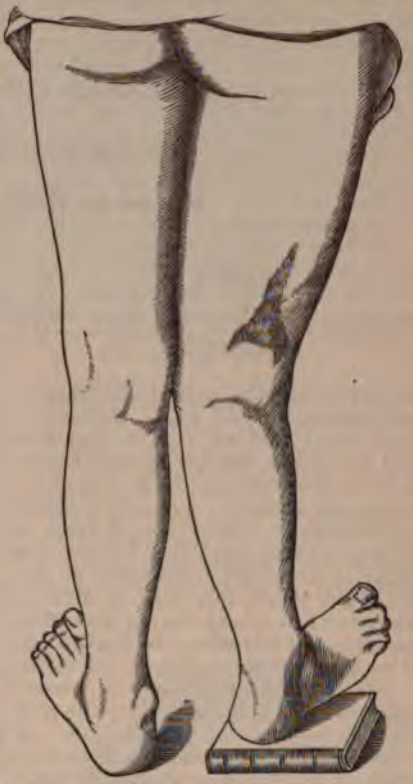


From a case in which three inches and a half of the shaft of the femur had been removed subperiosteally. The knee became ankylosed from the extension of suppuration into the joint. Fig. 659 shows the amount of the resulting shortening, which is confined entirely to the femur. The cicatrix on the inner side is the mark of an abscess. The posterior view of the limb shows the position of the wound from which the bone had been extracted, and the deformity produced by the ankylosis.

sion appears to me to be indicated, and should be performed at the earliest possible period. Many of these cases terminate in the most gratifying manner; and a patient who would otherwise have been condemned to amputation, or have lost his life by pyæmia, rapidly recovers from the profound surgical fever which accompanies this complaint, and regains a very useful, though somewhat shortened limb. In less acute cases, where the amount of bone which has perished is smaller, and the surgical fever does not run so high, the expectant treatment is certainly justifiable, and may often be advisable.

DISEASES OF THE JOINTS.

BY ATHOL A. JOHNSTONE, ESQ.

Revised by E. H. BRADFORD, M.D.

PART I.

DISEASES COMMON TO ALL THE JOINTS.

IN estimating the nature and importance of diseases of the joints, we have to bear in mind that we have to deal with varied structures, distinct in their formation, their functions, and their pathology, but all so far united for a special purpose that disturbance of any one of them is sufficient to derange the harmonious working of the whole. The study of diseases of the joints, therefore, involves to a greater or less extent that of the affections of the *osseous system*, the foundation, as it were, of the articulations; of *cartilage*, *fibro-cartilage*, or *membrane*, interposed between the bones to play the part of the buffers in the railway-train; of *fibrous tissue* or *ligaments*, the coupling-chains; of *synovial membranes* with their *synovia*, the lubricating boxes and grease by which the friction is diminished; as well as of *connective* and *adipose tissues*, which serve as packing material to fill up the hollows. External to the joints, moreover, but still playing an important part in their mechanism, are various muscles with their tendons, as well as synovial bursæ, the pathological conditions of which in their relation to the joints cannot be entirely omitted or passed over.

It is only since the investigation of the diseases of the joints has been pursued in relation to their structural origin (for which we are mainly indebted to the acute intellect and philosophical spirit of Sir B. Brodie), that any precision of diagnosis has been arrived at, any really physiological system of treatment been adopted. The diseases of the joints are no longer lumped together under the vague denomination of "white swelling," but referred, with more or less certainty, to the tissues in which they commenced, and connected with the pathological changes which those tissues are found to have undergone. It must, however, be admitted that when disease has advanced to a certain stage, so many of these structures are likely to be involved, that an accurate allotment of the symptoms to their respective sources would be useless even if it were possible; so that, practically, we have often to disregard minute anatomical distinctions, and consider the case mainly as regards its severity and probable termination. It may be remarked, too, that the separation of joint-diseases into those which affect the synovial membranes or ligaments, the bones, and the cartilages, is more obvious and more practically useful in adults, in whom these structures have arrived at their full growth, than in children, in whom they are still in process of development. As Mr. Hilton justly observes, "in childhood the separate and distinct disease of the articular structures can seldom be recognized with any useful precision during life."[1]

The limits assigned to this essay are evidently insufficient to allow of any complete or comprehensive study of these varied diseases; no more than a sketch can be attempted; but that sketch, it is hoped, may be found sufficient for all practical purposes.

Anatomically all joints are not alike, being divided into the comparatively simple *synarthrodial* articulations, or those devoid of a synovial membrane, and the more complicated *diarthrodial*, in which a synovial membrane exists. Pathologically a similar distinction may to a certain extent be drawn, and the affections of the diarthrodial articulations may conveniently be separated from those of the synarthrodial, which will receive such notice as may be considered necessary in the latter part of the essay.

DISEASES OF THE SYNOVIAL MEMBRANES—SYNOVITIS.

Synovial membranes are liable to inflammation, forming what is usually, though not perhaps very correctly, termed *synovitis*.

The inflammation which attacks a synovial membrane may be of the ordinary character, or it may be modified by certain constitutional conditions. Common synovitis occurs, in many cases, as a local affection from the direct irritation of mechanical injury, or results from undue exercise and exposure of the joint to atmospheric influences; it may also be induced by disease which has involved the adjoining tissues. This form of inflammation is generally confined to a single articulation.

---

[1] See also Holmes, Surgical Diseases of Children, p. 411. [For a different opinion, see Volkmann, die Fungöse Gelenkentzündungen, Klinische Vorträge, xv., 168, 169.]

The constitutional conditions which modify the character of the inflammation may be more or less permanent, and even hereditary. Sometimes we find the patient presenting evident marks of *scrofula*, and the local disease sharing in the peculiarities of that affection; in other cases, and principally in the poorer classes, who are ill-clad and unduly exposed to variations of temperature, the *rheumatic* diathesis is apt to prevail; whilst in those who live luxuriously, the local inflammation may be preceded or accompanied by various symptoms of disordered digestion, indicating the presence of an unusual quantity of uric acid in the system, or the existence of the *gouty* diathesis. The constitutional modifications, on the other hand, may result from causes which are obviously temporary. A peculiar form of synovial inflammation, for instance, may occur unexpectedly after parturition, or following some operation, in those in fact who are suffering from what is termed *pyæmia;* or it may take place suddenly during the progress of urethral discharge, when it is distinguished by the name of *gonorrhœal rheumatism;* or, finally, it may manifest itself during the existence of *venereal* poisoning. In all these modifications of inflammation, it may be remarked, there is a considerable chance of the topical disease manifesting itself in more than one articulation.

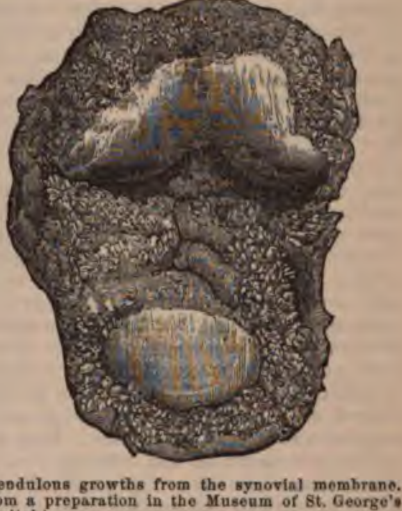
It will be convenient to commence with a description of the *simple* form of inflammation of a synovial membrane, and its consequences, and afterwards to notice briefly the peculiarities presented by synovitis when *scrofulous*, *rheumatic*, or *gouty; pyæmic*, *gonorrhœal*, or *syphilitic*.

Acute synovitis.—Synovitis may be acute or chronic. Acute synovitis, arising in the membrane itself from the causes already alluded to, occurs more frequently in adults than at an earlier period of life, in males than in females.

Pathological anatomy.—The simplest changes which result from inflammatory action consist in increased vascularity of the membrane, especially of its plicæ vasculosæ, followed by increase in the amount of the synovia, and some alteration in its healthy composition. A little later, we find the products of inflammation either effused into the synovial cavity, mingling with and usurping the place of the normal secretion, or situated in the texture of the membrane and in the immediately contiguous tissues. The effusion into the joint-cavity may consist of serum, mixed with shreds of synovial epithelium, and a variable amount of organizable lymph, giving rise to false membranes connected with the walls of the cavity or floating in the secretion; some of the coloring constituents of the blood may also be present. In a large number of cases the inflammation is arrested before much mischief occurs; the vascularity of the membrane diminishes, the effused fluids are absorbed more or less completely, and the joint is restored to its original condition; or it may be left more distended than natural, and liable to fresh effusion; or a certain amount of thickening and loss of mobility may remain permanently.

In other cases, however, further changes occur within the joint, giving rise to villous or fringed processes, extending, perhaps, over the cartilages, which may still be found beneath them. At the same time a similar action takes place on the outer side of the membrane, increasing the amount of thickening and consolidation of the capsule. If the inflammatory action still proceeds unchecked, the fluid effused into the joint becomes turbid, and pus is formed, at first scantily, but afterwards in larger quantities; the other structures entering into the composition of the joint become involved in the diseased action; the articular cartilages are

Fig. 661.



Pendulous growths from the synovial membrane. (From a preparation in the Museum of St. George's Hospital.)

affected, ulcerous excavations extend through their substance, and the articular extremities of the bones participate to a greater or less extent in the disorganizing process. The parts outside the joint-cavity undergo similar changes; degeneration takes place in their newly-formed materials, and abscesses arise there, communicating with the joint by ulceration extending through the capsule, or making their way to the surface by means of sinuses. The ligamentous structures become thickened or softened, or otherwise altered, so as, in some instances, to be no longer capable of holding together the bones, which may thus become completely or incompletely dislocated.

Symptoms.—The leading symptoms are those of inflammation generally, varying in degree with the amount of synovitis present, with the cause inducing it, with the particular constitutional condition, and with the individual joint affected. The amount of inflammatory fever depends upon the character and extent of the synovitis, and the importance of the articulation, being generally most marked when the hip-joint is the seat of the disease. Locally, we have *pain*, usually of considerable amount, increased by any movement of the part, and often characterized by a feeling of distension. It may be noticed also that the pain in articular inflammations, as in those of some other organs, is not always referred to the region in which the disease actually exists. In diseased hip, for instance, the suffering may be experienced mainly in the knee, giving rise occasionally to mistakes on the part of the careless observer. There is *swelling*, varying with the amount of effusion into and round the joint, and taking the shape not of the articular extremities of the bones, but of the distended synovial capsule, modified by the degree of resistance afforded by the surrounding structures. *Fluctuation*, at least in the more superficial joints, is usually distinct, becoming less so if the disease is prolonged and the inflammatory products acquire a more solid character. *Heat* and *redness* are more or less evident, according to the situation of the joint affected, its proximity to the surface, and the degree in which the tissues external to the synovial membranes are involved. The *position* which is unconsciously assumed in acute articular inflammation is often characteristic of the affection and of the particular joint implicated. To alleviate suffering, by securing rest, the limb becomes more or less rigidly fixed by involuntary contraction of the muscles in its neighborhood, but in addition to this rigidity, there is a strong tendency for the joint to become flexed, and for this flexion steadily, though gradually, to increase unless arrested by the surgeon. It has been supposed that the rigidity and flexion are due to over-distension of the joint-cavity by fluid; but the ease with which the joint can be moved, and the increased flexion relieved when chloroform is administered, points rather to undue muscular contraction. The most rational explanation appears to be that given by Mr. Hilton, in his valuable work On Rest, viz., "that the irritated or inflamed condition of the interior of the joint (say the knee-joint), involving the whole of the *articular nerves*, excites a corresponding condition of irritation in the same nervous trunks which supply both sets of muscles, extensors, and flexors; but that the flexors, by virtue of their superior strength, compel the limb to obey *them*, and so force the joint into its *flexed condition*."[1] At any rate the effect produced, that is, the position assumed by the limb, is practically of great importance, for it is capable of maintaining or aggravating the disease at the time, as well as of giving rise ultimately to great embarrassment in the event of anchylosis occurring.

In the majority of cases of uncomplicated synovitis, the inflammation speedily subsides, the fluid is absorbed, and the part returns to its normal condition. In others, however, the joint remains somewhat swollen, the synovial membrane is thickened, and the mobility of the part diminished, whilst the patient is left very liable to relapse from exposure to any of the exciting causes of synovitis. Or the acute symptoms may simply diminish, and without any interval of restoration to health the disease may assume the chronic form to be subsequently described. In a certain number of cases, unfortunately, the inflammation, instead of subsiding, increases in severity, and the disease is no longer confined to the synovial membrane, the cartilages and other structures becoming involved, in the manner to be more minutely described hereafter. Such extension is marked by fresh and excruciating suffering, by painful "jumping" of the limb, as well as by crepitus on moving the joint, as the cartilages become destroyed, and is followed or attended in a large proportion of cases by suppuration.

Acute articular abscess.—Suppuration in a joint, however, occasionally occurs also *directly* as a consequence of acute synovitis, the effect frequently of some injury, or, in children especially, as the result of acute inflammation supervening on chronic disease of the joint. In this acute form of joint-disease, whether we assign the synovial membrane proper, or some other of the varied textures with which it is more or less blended, as the starting-point of the disease, we may *suspect* the formation of matter, if the inflammation run very high; if one or more rigors occur, followed by exacerbation of the pain and general suffering; and if the tumefaction increase and take on a more decidedly phlegmonous character which extends to the surface. [There seems to be some doubt as to the fact that in chronic joint affections suppuration is usually preceded by a febrile onset. König states that after a series of careful thermometric observations he is convinced that suppuration is always preceded in chronic arthritis by fever. Schede, however, reports that the temperature curve is of no value in fungous arthritis.[1]] The constitutional disturbance will now be great, the pulse rapid, and the character of the fever will be altered, assuming somewhat of a typhoid form. When suppuration has occurred within the joint, and the case progresses unfavorably, the parts around become speedily affected. Abscesses are formed in the surrounding areolar tissue; at first, perhaps, separate from, but soon communicating with the articular cavity. The fibrous tissues become softened and yield, the skin gets implicated, and openings form communicating with the joint, and discharging a more or less unhealthy pus. When much disorganization has taken place within the joint, the most favorable issue to which we can look forward is discharge of the matter, and union of the opposed articular surfaces. The health may now improve. The swelling subsides, the discharge diminishes, and at last ceases, the sinuses heal up, the joint-cavity is obliterated, being filled with newly-formed connective tissue, and the limb is stiffened or completely anchylosed. If, however, the constitutional powers give way, the patient may be worn down by the severity of the pain and profuse discharge; the removal of the source of irritation, by excision or amputation, becomes necessary, or where this is impracticable, life is at last extinguished.

---

[1] Hilton, On the Therapeutic Influence of Rest, p. 156.

Chronic synovitis may be simply inflammatory in its character, though it occurs more commonly perhaps as a modification of the inflammatory process, dependent on certain constitutional cachexiæ, such as scrofula, syphilis, gout, or rheumatism. In some cases the distinctive characters of each of these varieties are clear and well defined; and no difficulty is experienced in assigning the affection to its appropriate place. In others, however, the boundary-line is not always drawn with precision; and the surgeon finds in these diseases, as in most others, that the definite descriptions necessitated in books are not always borne out in practice. Just as acute disease melts by insensible gradations into the chronic, so the constitutional modifications of inflammation are often imperfectly or scarcely marked. At the bedside of the patient, the surgeon must work out for himself many details; and every case will still offer some special employment for his intellectual investigation. The author can only point out, as it were, the leading types; he who attempts more bewilders the reader instead of assisting him.

Acute inflammation of the synovial membrane, imperfectly treated, may by degrees assume the chronic form; or commencing without any great activity in its symptoms, the inflammation may pass into a chronic condition; in the latter case, however, the probabilities are very much in favor of the existence of some constitutional taint. The joint is sometimes much distended with fluid; and the synovial membrane itself, in protracted cases, loses more or less of its natural structure, is over-vascular, and permanently thickened, or converted into a firm and gristly substance. The disease may gradually yield, or it may remain stationary in this condition for a considerable time, and then, under the influence of fresh inflammation, the joint may ultimately become totally disorganized.

The symptoms are much the same as in the acute form of disease, and far less severe in their character. The constitutional disturbance is comparatively little felt. There is swelling, sometimes to a considerable extent, more or less pain is experienced, and the movements of the joint are often very greatly impaired. In some instances a peculiar crepitus or crackling is felt, or a sensation is communicated to the hand as if a number of loose bodies existed in the joint, depending, perhaps, on effusion of plastic material into the cavity, similar to that noticed in inflammation of the bursæ and tendinous sheaths. The simple form of chronic synovitis—the form, that is, not connected with any constitutional taint—usually terminates favourably unless neglected, as is occasionally seen in the laboring classes, when attack after attack may occur till at last the joint is destroyed, or life itself sacrificed. In cases, too, of long standing, where great induration of the soft tissues has occurred, complete restoration to a healthy condition becomes at best difficult, and relapses into a state of sub-acute inflammation are of frequent occurrence.

[[1] London Med. Record, 1878, p. 221. From Berl. Klin. Wochenschrift.]

Treatment of acute synovitis.—The treatment to be adopted is partly general, partly local. If the inflammation runs very high, and the patient is strong and plethoric, it may be necessary to take blood from the arm; at any rate, a brisk mercurial purgative, followed by salines, with antimony, and perhaps with colchicum, will be advisable, or in some cases it may be expedient to place the system rapidly, but for a short time, under the influence of mercury. Where the patient is less robust, any bloodletting had recourse to should be local; and in all cases, though it will be desirable to keep the liver acting by combining taraxacum with the saline medicines, or by administering occasionally some preparation of mercury, violent purgatives should be avoided, on account of the disturbance to the limb which they necessitate.

The primary and essential condition of the local treatment is complete *repose.* When the inflammation is of moderate extent, mere rest in bed, with the joint supported by a partially distended air- or water-cushion, will be sufficient. Where the inflammation is severe, and danger of permanent mischief threatens, more decided mechanical support is required. The position to be adopted varies with the individual joint, but in all cases must be that which keeps no ligament, and no part of the synovial membrane, on the stretch, and which, in the event of anchylosis occurring, will allow the limb to be used to the greatest advantage. Supposing the articulation to have already assumed an improper position, it is better to put it right *at once*, even if the existing inflammation is acute; for in unnatural positions the different parts of the joint are kept in a state of undue pressure or of undue tension, either of which interferes with healthy nutrition, and so opposes the curative process. Under the influence of chloroform [or ether], the replacement can, at this time, be readily effected.[1] [The experience of Bonnet appears to demonstrate the safety of the procedure of forcible straightening, while inflammation is present. (Maladies Articulaires.)[2]] The splint used should be well adapted to the limb, and be of *sufficient length;* in many cases it is absurdly short, giving no real rest to the joint, and allowing the weight of the parts below to drag upon the ligaments, and tend to produce deformity. In disease of the knee-joint, for instance, to give effectual support, the splint should extend very far up the thigh, and be furnished below with a foot-piece, to prevent the tendency of the foot to fall outwards or inwards, and so produce a corresponding twist of the affected articulation. The points here insisted upon are, of course, applicable not merely to cases of synovitis, but of all diseases of the joints, in which absolute rest is demanded.

Local depletion may be required to an extent determined by the acuteness of the inflammation and the vigor of the patient. If leeches are applied, it must be remembered that they act not merely by the abstraction of blood they give rise to, but also as derivatives, in consequence of the irritation produced by the bites. The application of leeches immediately over a *superficial* joint may tend, consequently, to increase the inflammation instead of diminishing it. In acute synovitis of such a joint as the knee, therefore, it is better to apply leeches at some short distance *above* the joint, so as to empty the distended vessels below. The same observations would, of course, apply, should cupping be employed instead of leeches.

After, or in many cases in place of, the local depletion, various emollient applications may be used. As a general rule, warm fomentations and poultices are the most successful in relieving pain. Occasionally, however, cold is more grateful to the patient. Whichever is employed, uniformity of temperature is much to be desired; the joint should not be exposed to frequent changes, but the applications should be maintained constantly at or near the same standard. It is on this principle that wrapping the joint in cotton wool, or covering it with ointments which exclude the air, is often of service. If cold be applied, it may be used as directed by Dr. Esmarch,[1] in the form of ice contained in bags of vulcanized India-rubber (far preferable for many reasons to bladders), separated from the limb by a piece of lint. If this prove too heavy, a simple apparatus may be contrived, by suspending, at a suitable angle, from the cradle placed over the affected limb, a bottle containing cold water, in which a few threads are partially immersed, with their ends hanging out of the mouth of the bottle; these, by capillary attraction, will keep up a constant drip upon a piece of lint covering the inflamed joint, and the supply of fluid may be so regulated, by varying the number of threads, as just to compensate for the loss by evaporation, and prevent the rag from ever getting dry. Such an arrangement I frequently used with advantage at the Hospital for Sick Children, both in cases where acute inflammation already existed, and in others where its occurrence might be anticipated in consequence of operations. The cold should be maintained without intermission, as long as any abnormal increase of temperature exists, provided it appears grateful to the feeling of the patient.

---

[1] As Mr. Holmes Coote, at page 85 of his work On Joint Diseases, has quoted these remarks for the purpose of adding, "To this practice I most strongly demur," I may be allowed to cite the very judicious and forcible observations of Mr. Hilton respecting the mischievous and destructive effect he has over and over again seen produced by allowing the joint to assume or retain the fixed and flexed position induced by involuntary muscular contraction, "resulting not seldom, I may say, from procrastination, or inexcusable want of courage on the part of the surgeon to rectify it, or from his yielding too easily to the importunities of the patient or his friends, in order to avoid giving pain to the patient. From the time when the limb begins to be flexed starts the mischief, which by-and-by cannot be controlled." And again, after relating two cases in which amputation had to be performed: "It seems to me that it is a great mistake not to correct it *at once* when they see an inflamed knee or other joint beginning to be contracted or flexed. I believe their duty is to prevent the increase of the flexion, and so avert the condition which, at all events, led to the necessity for amputation in these two cases."—Hilton, On the Therapeutic Influence of Rest, pp. 161–3. I need not say how heartily I concur in these remarks, in which, it may be noticed, the very words employed in the text about correcting the improper position "at once" are adopted by Mr. Hilton.

[[2] See also Bauer, Lectures on Orthopædic Surgery.]

Treatment of acute abscess of joints.—If there is reason to believe that acute inflammation of the synovial membrane has proceeded rapidly to suppuration, the fact may be verified, at least in the more superficial joints, by the introduction of a needle-trocar. Supposing matter to be found, if situated outside the joint an early incision may prevent the pus making its way into the joint-cavity; and if inside the articulation, the urgency of the symptoms will seldom allow of much delay. It is better, therefore, when the situation of the joint admits of it, to evacuate the matter as early as possible by a free incision, which may be made under the protection of lint steeped in carbolic oil, and the wound afterwards dressed on the antiseptic principle, as practised by Mr. Lister.

[*Incision and drainage of the joints.*—The advantages of the antiseptic system in surgery is well demonstrated in the change thereby produced in the treatment of joints with effusion, or inflamed joints. Bonnet has stated that suppuration always follows an opening in a large joint. At the present time experts in antiseptic surgery incise joints (with or without suppuration), and the most remarkable success is reported. Mr. Lister has recently treated a simple fracture of the patella by opening the knee-joint, inserting a drainage-tube, and wiring the fragments. The patient recovered perfectly in eight weeks, with perfect motion at the joint. Scriba, of Baden, recommends incision and drainage of the knee-joint in chronic serous inflammation, in chronic disease of the knee-joint with granulation, with effusion, and no disease of the bone, in acute purulent affections of the joint, and in acute serous affections where the pain is severe and continued. He reports six cases where incision of the knee-joint was done antiseptically, and all recovered perfectly. Heinecke reports ten cases where the joint was incised and washed out. In two the operation was done for suppuration caused by a wound. In seven cases the result was a cure with perfect motion. In three suppurative knee-joints (two complicated by disease of the bone) there was only limited motion on recovery. Of the seven other cases one was an acute serous inflammation, one hydrops articuli, one sanguineous effusion, three were punctured wounds of the joint, one was removal of a loose cartilage. Schüller reports two cases of antiseptic incision and drainage of the knee-joint. Recovery followed. In the other the suppuration at the knee-joint followed an attack of erysipelas, and the patient died after the incision. Rinne reports eleven cases of knee-joint affections tapped with a trocar and washed with a three per cent. solution of carbolic acid. In five of these no reaction followed; in four there was slight fever; nine were completely cured; one died of tuberculosis; one was improved, but did not gain perfect motion. Ranke reported seventeen cases of open wounds of the larger joints, treated antiseptically; fourteen recovered with motion at the joints. In three the result was anchylosis, but in these antiseptic treatment was not begun until after suppuration had been established. These figures show remarkable success, and leave the impression that incision into the joint is an almost harmless procedure. In the practice of the editor, however, a death from shock followed twelve hours after incision into the knee-joint. The operation was done with the most thorough antiseptic details, for suppurative disease of the knee-joint; but the patient was a child three years old, unable to bear operative interference of any sort.[1]]

[1] On the Use of Cold in Surgery, New Syd. Soc., 1861.

[[1] Scriba, Berlin K. Wochensch., Aug. 6, 1877; Heinecke, Deutsche Zeitschr. f. Chirurgie, 1878, 10th Bd., p. 296; Schüller, Deutsche Med. Woch., Nov. 24, 1877; Rinne, Centralblatt f. Chir., Dec. 8, 1877; Ranke, Ibid., 29, p. 480, 1878; Schmidt's Jahrbücher,

The opening in such cases is usually attended with marked relief; but fresh incisions may afterwards be made, or a drainage-tube introduced if any obstacle to the exit of pus shows itself. During this time the most perfect rest must be observed, and the limb maintained accurately in position by splints of sufficient length, moulded, if necessary, to the requisite form. Great attention must also be paid to the general health, and the strength supported as the activity of the inflammatory fever subsides.

If the matter within the joint decomposes without escaping freely, absorption of some of its putrid constituents may occur, showing itself by the irritative or typhoid character of the fever. In many cases life is now so evidently at stake, that removal of the diseased part either by amputation of the limb, or, in exceptional instances, by excision of the joint, becomes imperatively called for. In other cases, after providing as far as possible for the free evacuation of the pus, weak iodine injections may be used, not merely to modify the action of the secreting membrane, but also to improve the character of the matter. With care and attention on the part both of the surgeon and the patient, acute suppuration of joints from synovitis may often be expected to terminate favorably, especially in children; but as more or less stiffness of the joint must be expected, special attention should be paid from the first to the position of the limb, instead of waiting, as is sometimes done, till ankylosis has taken place, to remedy the deformity which has been allowed gradually to arise.

Treatment of sub-acute and chronic synovitis.—Instead of giving rise to the formation of abscess, the acute inflammatory symptoms usually subside. As this change occurs, the antiphlogistic treatment is modified; some blood may still be abstracted by leeches applied directly over the part, and cooling applications may be used, or counter-irritation may be had recourse to, in the form of blisters, to produce a discharge of serum from the vessels of the skin. Blisters may be used earlier in inflammation of the deeper-seated joints than where the superficial articulations are implicated; for in the latter the small amount of intervening tissues allows the irritating action to be propagated to such an extent as sensibly to affect the synovial surface, acute inflammation of which may be again excited under the influence of too severe or too early a stimulus. In synovitis, therefore, of the superficial joints, blisters should not be applied too hastily, and when used may be placed some little distance above the inflamed spot; it is better also to employ a succession of "flying" blisters rather than to keep *one* open by irritating applications. Following the blisters, or in place of them, various stimulating liniments may be used, or the parts painted with concentrated tincture of iodine. As the inflammatory symptoms subside, in those cases especially where some thickening of the membrane has occurred, we combine a moderate amount of compression with our support of the part; this may be done by applying alternate layers of bandage and adhesive plaster with or without camphorated mercurial cerate next the skin, in the way described as "Scott's bandage." [The most convenient method of employing compression in joint effusions is by means of a rubber bandage.[1] (Surgical uses of the Strong Elastic Bandage, by H. A. Martin, M.D.) Less efficient for this purpose are flannel bandages, and the bandaging of dry compressed sponge, which if bound tightly around the joint, will expand when wet and exert compression on the joint.[2] Another way has been suggested, viz., to use compression by means of rubber bags placed around the limb, and then filled with water.] Sometimes the bandage is starched, but care should then be taken, if any fresh outburst of inflammation occurs, that the bandage can be promptly removed, if necessary, by the patient. In some cases it is useful to employ splints made of cow-hide, softened in warm vinegar, moulded to the form of the joint, and fastened on the limb after having been lined with chamois leather. Many similar contrivances will probably suggest themselves to the surgeon's mind.

If rest be a primary necessity in the acuter stages of inflammation, a time comes at last when this has to be discontinued, and passive motion of the joint substituted in its place; but the exact time when this change is to be made, often requires great judgment and discrimination. The mere presence of pain on motion is not always decisive of the necessity of rest, for in some cases, after long confinement, pain and aching are actually relieved by free and even strong movements.

A distinguished artist, for instance, came under my care for disease of the right wrist-joint following exposure to cold and wet.

1877, Bd. 174, p. 268; Lucas-Championnière, Gaz. Med. de Strasbourg, Sept. 1, 1877; Lancet, 1875, vol. ii., 311; Brit. Med. Journ., March 31, 1877; Edinburgh Med. Journal, Sept., p. 193, 1875.]

[1] [Transactions Am. Med. Assoc., 1877.]

[2] [See also Cohn, Allg. Med. Cent. Zeit., Dec. 5, 1877, p. 1211.]

The inflammation had been severe, and the joint had been kept at perfect rest for several months, but still great aching and pain were complained of, the part was puffy, stiff, and sensitive, though not warmer than natural, and the patient in despair of ever again being able to follow his profession. With some degree of caution I removed the splints and employed passive motion, gradually increased in force, strong friction to the part, and localized galvanism to the individual muscles of the forearm, which had become rigid from confinement, like the joint itself. The pain subsided under this change of treatment, and by degrees perfect motion was regained, so that the artist has been enabled to resume his profession with no impairment of his technical skill.

Perhaps the best indications for substituting motion for rest in those cases in which pain continues severe after active disease has subsided, are the comparative low temperature of the joint, and the tendency of the integuments to become dusky and puffy.

[M. Verneuil has recently strongly protested against the use of passive motion as a preventive to ankylosis. "Ankylophobia," as he terms it, has no real basis. Ankylosis results from the processes of inflammation, and rest complete and absolute is the best antiphlogistic; no motion should be allowed until the patient is able to exercise the limb, and all that can be gained will be gained in that way. He does not deny that cases are met where *brisement forcé* is of use, but believes that these do not belong to joint affections proper, but to periarticular troubles and the result of previous inflammation. The use of passive motion to prevent ankylosis in the course of inflammatory troubles, as recommended by Bonnet, he believes to be injurious.

The efficacy of massage, which includes passive motion, in sprains of the joints cannot be questioned, and the method of its application has risen from the level of empiricism to that of a well-established rational therapeutic agent in the treatment of the periarticular changes which follow or accompany sprains. Its employment has been advocated in acute traumatic synovitis, chronic synovitis, hydrops articuli, chronic rheumatic arthritis, and in the sequelæ of acute and chronic inflammation of the joints. It is claimed that massage is useful in all the forms of joint trouble where a cure may be expected; and that by its employment a recovery can be more quickly gained than without it.[1]]

The treatment sketched out has been that proposed for disease of the synovial membrane itself; the treatment of those cases in which the bones and cartilages become involved will be alluded to subsequently, in the sections treating of diseases of those tissues.

Dropsy of joints.—We occasionally meet with cases in which the synovial membranes are very greatly distended with fluid, whilst few or no other symptoms of inflammation are present. The affection, therefore, has been compared to dropsy of serous membranes, especially to that of the tunica vaginalis testis forming hydrocele, and has received the special name of *hydrops articuli*. I have placed it, however, immediately after ordinary synovitis, because in almost all the cases where an opportunity has been afforded of examining the joint, the lining membrane has been found somewhat thickened and unusually vascular, especially in the situation of its vascular processes. The fluid differs from ordinary synovia, being transparent and of a yellowish color, but presenting no appearance of "threads," though it coagulates on the application of heat; in fact, it closely resembles the fluid met with in ascites or in hydrocele. All synovial membranes are not equally subject to dropsy, which usually affects those of considerable extent, and in which the secretion is naturally abundant. It is most frequently found in the knee, sometimes in the elbow, very seldom in any other articulation. Hydrops articuli is scarcely ever a primary affection. It may follow an acute attack of synovitis, and is apt to recur in persons of weak and irritable constitutions, when once the membrane has been over-distended. In such persons the immediate attack may be induced by exposure to cold or very slight violence, or even by some less obvious constitutional disturbance.

The effusion takes place very rapidly, and forms a tumor, whose limits are those of the synovial capsule. Its character may generally be easily recognized by the shape of the swelling and its ready fluctuation. There may be some slight symptoms of inflammation present; but usually, though the limb is somewhat stiff; it may be used with scarcely any pain, even from the first, and the parts external to the capsule show no traces of redness or œdema. From thickening of the joint due to effusion of plastic lymph, hydrops articuli is distinguished by the fluc-

Record, Aug. 11, 1877; Aug. 16 and 23, 1879; Weiss, Wiener Klinik, 1879, 11th and 12th Heft; see also Schmidt's Jahrbuch., Bd. 175, 1877, No. 7; Berghmann, Viertel-Jahrschrift f. d. prakt. Heilkunde, 1876; Verneuil, discussion on treatment of Joint Disease, Med. Times and Gaz., Oct. 18, 1879, p. 454; Gaz. des Hôpitaux, 1879, p. 1053.]

tuation, which, as M. Bonnet remarks, is best recognized by placing one hand above and the other below the tumor; if they are placed transversely, the displacement of the muscles or tendons may be mistaken for the movement of fluids. From abscess of the joint, it may usually be distinguished by the condition of the soft parts around, as well as by the constitutional symptoms, though it occasionally happens that the true nature of the effusion can only be determined by puncture with a needle. The prognosis in these cases is most favorable; at least, the other structures of the joint seldom become involved, though the disease itself may be difficult of cure and very prone to relapse, especially in cases of some standing.

Treatment.—If any inflammatory symptoms are present, these must first be subdued by the ordinary constitutional remedies; by leeches and fomentations, or by cooling lotions. When all traces of inflammation are subdued, and the affection has assumed the chronic form, the joint may be blistered, or painted frequently with a strong solution of iodine; this may be followed by compression by means of adhesive plasters and bandages, accompanied by stimulating and mercurial applications directly to the skin, for the purpose of promoting absorption. If the case is recent, under such treatment the effusion may be expected to subside; but it will still be necessary to support the relaxed membrane by wearing a laced or elastic knee-cap for an almost indefinite period.

In old and neglected cases, on the other hand, the affection resists all ordinary treatment, and must either be abandoned as incurable, or further and operative measures had recourse to, the most promising of which are iodine injections, employed as in cases of ordinary hydrocele. Should it be considered advisable to have recourse to this plan, and the knee be the joint affected (as is most commonly the case), the spot selected for the puncture is that part of the synovial membrane which is situated above and external to the patella; the limb should be in the extended position, and the opening rendered valvular by pulling aside the skin before introducing the trocar, which should be only of moderate size. The fluid injected may consist of tincture of iodine more or less diluted. In a case of hydrarthrosis of both knees in which a permanent cure was effected by this injection, after all other treatment had failed, Mr. Goodall[1] used equal parts of the tincture and of water, whilst Schuh,[2] who has employed this treatment successfully in three cases, made use of one part of tincture of iodine to four parts of water. The quantity injected may vary from half an ounce to two or three ounces, the latter quantity being that recommended by Schuh. As much as possible of the fluid is allowed to escape, after being retained in the joint for about five minutes, and care taken to prevent any admission of air to the articulation. When the trocar is withdrawn, the cutaneous wound is coated with collodion. The immediate result of the injection is to produce a certain amount of inflammation; to prevent this from going too far, the limb must be retained in a state of immobility after the operation by means of a properly adapted splint, and the case watched carefully, so that antiphlogistic measures may be had recourse to if necessary. [The results of the injection of the tincture of iodine in the treatment of hydrarthrosis are: 1. A complete cure with preservation of mobility; 2. Cure with a certain amount of stiffness; 3. Complete failure: 4. Suppuration and injury to the joint. The first and last classes of results are said to be uncommon. From a few dissections of joints after the injection of iodine it would appear that the irritant did not bring about adhesions, but caused a change in the character of the synovial wall.[1]] This treatment is only suitable to cases of simple dropsy, uncomplicated with diseased conditions of the bones and cartilages, and would only be advisable when all other measures had failed, and much inconvenience was occasioned by the distended capsule.

[The antiseptic system of dressing wounds having rendered direct incision into the joint a much safer operation than was formerly thought to be the case, that method is likely to entirely supersede tapping with a trocar, and the injection of iodine. Aspiration of the knee-joint, a much simpler method, appears to be a procedure devoid of danger. Dieulafoy has been most active in introducing this mode of treatment. He reported (Gaz. des Hôpitaux, May, 18, 1878) 200 aspirations of the knee-joint, and regards the operation as a rational and efficient one. A rubber bandage is to be placed around the joint, leaving a spot uncovered for puncture. The point of election in the knee-joint is the external cul-de-sac, on a level with the upper border of the patella. Compression is used as soon as the fluid is evacuated. The aspiration is to be repeated in twenty-four hours if the joint refills. In some cases it is necessary to aspirate six or more times before cure.[1]

[[1] Panas, Nouveau Diction. de Med. et Chir., "Articulations;" see also Allg. Wien. Med. Zeitung, April, 1878, p. 178; Hydrarthrosis, Recherches sur le rôle de certaines influences dans le developpement; Grenier, Thèse de Paris, 1878.]

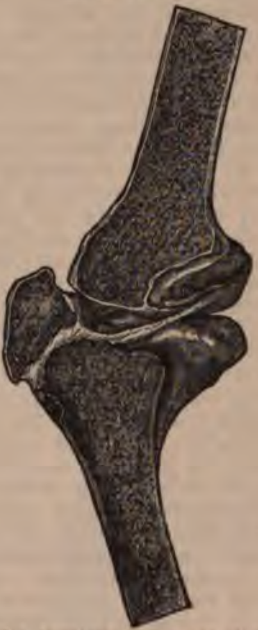
Seeligmüller[2] mentions a hitherto undescribed affection of the joint, an intermittent hydrops articulorum, usually affecting the knee, more rarely also the hip. In the majority of cases a swelling appears without febrile symptoms and from no known cause, and disappears, reappearing after a certain interval. The duration of the attack is usually four days, and the pause between the attacks from eight days to a fortnight. No treatment seems to be of avail.]

Scrofulous synovitis: pulpy degeneration.—There is a peculiar form of slow inflammation of the synovial membranes, which is sometimes described under the name of *gelatinous* or *pulpy degeneration of the synovial membrane*, but which appears to be inflammation of a chronic character, modified, possibly, by the scrofulous condition of the system. If we have an opportunity of examining the joint when the disease has advanced to a certain extent, the principal points which attract attention are the thickening of the synovial membrane, and the gelatinous or pulpy appearance which it presents. The vascularity of the membrane is increased, and the mass of its substance appears to be converted into a soft yellowish or light-brown gelatinous material, frequently of very considerable thickness. The articular cavity becomes diminished as the thickening extends upon the *internal* surface of the membrane; and as this extension goes on most freely in the loose synovial folds which surround the cartilages, these are often partially or completely buried and concealed beneath the new formation. A somewhat similar process occurs at the same time in the areolar tissue at the *outer* surface of the membrane, which becomes condensed and infiltrated with a corresponding pulpy substance.

The joint may remain in this condition for a considerable period, and then, under favorable circumstances, a process of restoration occurs, the new elements shrink or are absorbed, and the articulation is restored more or less perfectly to its former condition. More frequently, however, the disease makes further progress; the gelatinous thickening of the synovial membrane extends further over the cartilages, which become themselves secondarily affected in spots; though these spots are not, necessarily, at first, in *direct* relation with the altered membrane. The precise nature of the change which occurs in the cartilage will be considered in the description of the diseases which affect that structure; it need only be said here that the cartilage becomes more and more altered at the points first affected, and that intimate adhesion soon takes place between the granulation-tissue which these points present and the corresponding growth from the synovial membrane. The change in the cartilage is attended or followed by inflammation of the bone on which it rests; the articular lamella gives way in places, a communication between the osseous tissue and the interior of the joint is formed, and granulations spring up from the inflamed membrane lining the cancelli, which join with those already existing within the articulation. In the mean time matter has most probably been formed, which may be retained within the articular cavity, or may make its way to the surface by means of sinuses.

If the disease still makes progress, the gelatinous growth continues to extend in an outward direction, or it degenerates in patches, giving rise to fresh formations of matter in its own substance or in the ar-

Fig. 662.



Section of a knee-joint, the bones of which are united by ligamentous tissue after scrofulous disease. (From a preparation in the Museum of St. George's Hospital.)

---

[1] H. O. Marcy, Aspiration of the Knee-Joint, Trans. Am. Med. Assoc., 1879. Piechaud, Ponction et Incision dans les Maladies Artic., Med. News and Abstract, Aug., 1880, p. 498; Riedel, Hæmarthros, Centralbl. f. Chir., 1880, 10.]

[2] Berliner Klinische Wochenschrift, 1880, p. 106.]

ticular cavity; the constitutional powers now probably fail, the tissues of the joint, including the osseous, are still further destroyed, and amputation or excision is had recourse to, or the patient dies hectic. When, on the other hand, an improvement takes place, the new growth is directed inwards towards the articular cavity, which it tends to fill up. As the constitutional powers improve, the gelatinous material becomes firmer and more fibrous, it continues to contract, the cavity within it diminishes and is obliterated, the bones are united by a firm and solid substance, and the joint is ankylosed, as in the accompanying figure.

Symptoms.—Pulpy degeneration makes its appearance most frequently in early life, at or before the time of puberty, though no period of life can be said to be absolutely exempt from risk of its occurrence. In many instances the immediate attack can be traced to some slight accident or other local source of irritation; in others no such cause can be discovered, the attack appearing to commence, as we may say, spontaneously. It is characterized by a want of acuteness, even at its commencement, the earliest symptom noticed (supposing the disease to be in the lower extremity) being slight limping, followed by some swelling about the joint.

The nature of the affection is most clearly recognized in those joints which are the most superficial. In its early stages it is characterized by stiffness of the joint, and the presence of a soft, elastic, colorless swelling, occupying the whole extent of the articulation. The absence of genuine fluctuation should prevent the disease from being mistaken for dropsy or abscess of the joint; the size and doughy feel of the swelling distinguish it from simple synovitis; whilst its whiteness is opposed to the darker tint which is usually met with in malignant disease. The early stages of the swelling are usually accompanied with comparatively little pain, the disease in many cases being very insidious in its progress; in this respect, as well as in the shape of the swelling, which extends equally over the whole joint, instead of being specially manifest in the situation of one of the bones, differing from disease commencing in the cancellous structures. If the progress of the case is towards recovery, the swelling ceases to increase, solidifies slowly, and gradually diminishes in size, the pain at the same time yielding, and the condition of the general health becoming much improved. Even if arrested in this early stage, a considerable amount of loss of free movement of the joint must be expected, and great care taken that no recurrence of the symptoms is produced by too early exercise.

When the disease advances, the enlargement and stiffness of the joint increase, the pain, which was previously perhaps little more than a sense of aching or feeling of fulness, becomes more marked and altered in its character, being now described as a "jumping," "gnawing," or "starting" pain, and felt with special acuteness at night-time. This change may be considered a sign that the disease is no longer confined to the synovial membrane; that the cartilages are becoming ulcerated, or rather, more strictly speaking, that the bone on which those cartilages rest is itself participating in the inflammatory action. Another symptom, which would indicate a considerable amount of destruction of cartilage, is the existence of crepitation on any movement of the joint by the patient himself or by the surgeon. This crepitation, however, it should be recollected, may disappear or be masked at any time in consequence of soft and extensive granulations rising from the bones, and preventing their articular surfaces from rubbing on each other. The limb is now in danger of becoming rigidly fixed by spasmodic contraction of the muscles, causing it to assume positions varying in the different articulations, but all tending to produce future embarrassment, unless carefully watched and guarded against.

Before the disease has advanced to this point, in the majority of cases suppuration has occurred, either infiltrating more or less extensively the gelatinous mass, or limited so as to form circumscribed abscesses in its substance, or accumulated in the remains of the synovial cavity. If collected within the joint, there will be a general increase of the swelling, with throbbing pain, and perhaps fluctuation, attended by febrile disturbance to a greater or less extent. After a time the matter makes its way through the softened walls, and "pointing" takes place at spots determined by anatomical peculiarities referable to the individual joint; the sinuses so formed presenting subsequently large and flabby granulations. When the abscess is situated in the gelatinous mass itself, the increased swelling, instead of being general, takes place at any part of the mass which may happen to be the seat of the degeneration, and the opening forms at or near this point. In most cases, however, even when the joint-cavity was originally free, it becomes involved subsequently in the parietal abscess.

In proportion to the deterioration of the constitution will be the extension of the destructive action. The ligaments and neighboring parts become softened and destroyed, the altered extremities of the bones are no longer firmly united to each other, and in this condition a partial or comple dislocation is occasionally produced under the influence of spasmodic muscular action; this dislocation being often attended with decided relief to the severity of the symptoms. If the constitutional powers improve, it is still possible for a process of repair and recovery to occur. The discharge in such cases diminishes, the openings contract and ultimately close, the skin resumes its natural appearance, while the swelling decreases and becomes more solid. The diminution in size of the joint continues till it becomes even smaller than it was before the attack, and the skin presents a peculiar puckered appearance around the articulation and at the seat of the cicatrices. The restorative process is of course attended with anchylosis, fixing the limb in the position it may have been allowed to assume.

This form of disease has generally been supposed to be strumous in its character, and connected with the scrofulous diathesis. Mr. Holmes,[1] however, has questioned its constitutional origin, and advanced many excellent reasons for doubting whether, in a large proportion of cases at any rate, chronic joint-disease may not simply be the result of some local injury or irritation, and essentially independent of any general cachexia, though strumous persons would be at least as liable to it as others. At any rate, as Mr. Holmes justly remarks, "whatever our views may be as to the pathological question, I think we must all agree that practically we have no such proof of the constitutional nature of any of these chronic joint-affections as should lead us to refuse to entertain the general question of operative treatment. Individual cases must be judged of by their own symptoms."

[The question of the "strumous" nature of chronic joint affections has lately attracted renewed attention. The two opposite opinions are well defined by the statement of Dr. Gross, that hip-joint disease could never occur unless a tuberculous diathesis were present, and that of Dr. Sayre to the effect that children in perfect health, with a personal and family history absolutely free from taint, may acquire disease of the spine or hip-disease from traumatism.

Schüller's experiments are interesting in this connection. He produced a state of artificial tuberculosis in a number of animals by the injection and forced inhalation of tuberculous material. On these animals, and on others in a state of health, he inflicted injuries, contusions, and sprains at the knee-joint. Recovery took place in the healthy animals, but in the tuberculous, the joints developed symptoms of fungous arthritis; this pathological condition was demonstrated on killing the animals and examining the joints. The joints of the healthy animals when killed were found in a normal condition, with the exception in some cases of evidence of extravasated blood and effusion in the process of absorption.

Dr. Gibney, after a careful examination of the clinical histories of 860 cases, found that in 56 per cent. no evidence of fall or injury could be ascertained. There was evidence in almost all of this class of patients of an inherited or acquired enfeebled physical condition. This was also the case in the remaining class where an injury appeared to be the original cause of the disease.

It is the experience of many that children in apparent health will be found suffering from the initial symptoms of joint affections—the same is true of patients with phthisis—and it is probably a fact that a "dyscrasia," as the term was used by the older pathologists, need not be considered as essential in the causation of either of these classes of diseases. But there is at present no evidence to warrant the belief that a fungous arthritis can be developed, without the existence of what may be termed "vulnerability." This may be an inherited physical defect, the legacy of a previous severe disease, or the result of faulty assimilation from imperfect nutrition.

A number of recent observers have established that in fungous arthritis, miliary tubercles are to be found in the granular articulations springing from the articular ends of the bones from the synovial membrane. It has been claimed that this is the characteristic lesion which distinguishes this form of joint disease from the less destructive simple synovitis, but the arguments to support this view are not as yet sufficiently strong to establish it beyond a doubt. The tubercle found in these granulations may be simply a secondary change common in the slow and chronic grade of inflammation occurring in "strumous" arthritis, and not the essential cause. As is well known, Bonnet claimed the existence of a form of tumor albus, distinct in its course, which he regarded as tuberculous. Tubercles were to be found in the epiphysis, or more frequently in the synovial membrane. König, however, regards it as established that arthritis fungosa is always the result of tubercles, which are more frequently found originally in the bone than in the synovial membrane. Lannelongue, however, describes an articular tuberculous synovitis, which he believes is much more common than is generally supposed.

---

[1] Surgical Treatment of Children's Diseases, pp. 424-7.

H. Hueter found that the injection of tuberculous matter directly into a joint produced a chronic fungous arthritis with miliary tubercles in the lungs, but none in the joint; injection of tuberculous matter into the peritoneal cavity caused tuberculosis of the lungs, but no change in the joints. To Köster belongs the credit of having first demonstrated the presence of miliary tubercles in fungous disease of the joints, or rather bodies resembling histologically in every particular what are universally characterized as miliary tubercles;[1] but as such cases have not come to autopsy until the osteitis was well advanced, it is impossible to say which is primary and which secondary.[2]

To generalize from this, as has been done, that the process in the joints is a local one, and not constitutional, is not warranted by the facts, as it is also not justifiable to conclude, that if a pronounced osteitis is recognized excision is demanded to prevent general tuberculosis.]

Treatment.—In our treatment we have to bear in mind that we are dealing with an affection originating in inflammation, but that inflammation of a chronic character and not improbably modified and altered by the strumous diathesis. Our efforts consequently have steadily to be directed to the improvement of the constitutional condition. Good air and plenty of it, warmth and light, attention to cleanliness and proper diet, are in all cases clearly inculcated. Where the tendency is to *scrofulosis*, the liver and bowels are usually sluggish, and require to be stimulated occasionally by tolerably brisk purges, combined with quinine; whilst in *tuberculosis*, purgatives must be given with caution, and be of the mildest character. In both cases tonics, and especially cod-liver oil, are of service; though these tonics should be administered with judgment, and in relation to the presence or absence of inflammatory fever.

The essential part of the local treatment consists in the joint being kept in a state of perfect and continuous *rest*, by means of splints, which should be well and properly made, and constructed so as completely to prevent any motion of the limb, and at the same time admit of any topical applications which may be deemed advisable. As the chance of ankylosis occurring is more considerable than in cases of ordinary synovitis, the *position* of the limb becomes of even greater importance, though it is to be regulated on the same principles. The splints may be made of leather or of pasteboard, or constructed of wire in the mode recommended by Bonnet and by Syme. If made of iron wire, a strong piece is bent to the shape of the limb, extending on both sides and united transversely to such an extent as to give the requisite degree of strength. The splint so formed is carefully lined with soft leather, or fitted with a kind of cushion, and will often prove highly useful. Too much attention can hardly be paid to the selection and adaptation of the splint in the first instance, and to the necessity of its being worn uninterruptedly for a very long period of time. If inflammatory symptoms are present, it may be necessary to employ a few leeches, or to use cooling or warm applications, as may seem expedient. As the inflammatory symptoms subside, counter-irritants may be had recourse to; these, however, should be employed with some degree of hesitation, and with the cautions previously pointed out as specially applicable to their action on the superficial joints. At the Hospital for Sick Children I became latterly more sparing in my use of them. Mr. Barwell,[1] however, strongly recommends the employment of the actual cautery in these cases, when the first symptoms of inflammation have somewhat subsided, but when some such action still continues, and enlargement is still going on. The iron is to be white hot, and applied in lines, about an eighth of an inch in breadth and three inches in length, parallel to the axis of the limb. Four such lines are recommended for the knee, two on each side of the patella, at least an inch apart; dry lint may be applied immediately after the cauterization. The advantage of this plan, according to Mr. Barwell, consists not merely in its acting as a counter-irritant, but also in the pressure produced subsequently on the subjacent parts by the contracting cicatrices. Extension by means of weights, as described in a subsequent part of this essay (see p. 267), is also of considerable service in many cases where the joint affected is in the lower extremity.[2]

Where the disease is confined to the synovial membrane, and has assumed an entirely passive condition, measures may be properly adopted to produce absorp-

tion of the indolent gelatinous mass. Such measures would obviously consist in *friction*, *passive motion*, and accurately applied *pressure to the part*. These means, as pointed out by M. Bonnet, may be freely adopted, but still with care and caution, and at once abandoned if symptoms of renewed activity in the disease show themselves. If any camphorated mercurial application is used to the part, along with the pressure, in the way described as "Scott's dressing," it should be employed in these cases very sparingly, and in a very diluted form; the joint, too, should be examined frequently, to make sure that no fresh attack of inflammation has occurred. As the case progresses towards recovery, friction and passive motion are more freely used, and the treatment assimilates to that of ordinary chronic synovitis. Should suppuration take place within the joint, the matter must be evacuated by free incisions made in depending positions, followed subsequently by slightly stimulating lotions to the sinuses, and moderate pressure to the joint, which is still to be maintained in a state of perfect rest, as well as in a suitable position. If the health give way, or the strength appear unequal to bear a long-continued discharge, and the circumstances of the case be such as not to admit of a prolonged use of the treatment which may be desirable, amputation of the limb or excision of the joint will often become necessary. Should improvement, on the other hand, take place, and cure by ankylosis be effected, we must be careful to employ passive motion in due time to prevent ossification, and maintain the uniting material in its fibrous condition.

Rheumatic synovitis.—In the description of synovitis, it was stated that this frequently arose from exposure to cold, or in connection with other causes loosely spoken of as rheumatic. The synovial membranes and parts about the joints are also liable to suffer in a special condition of the system by which the inflammatory process is materially modified, and which constitutes "rheumatism" properly so called. In acute rheumatism or rheumatic fever, the articular affection, although it may be severe and troublesome enough, is evidently dependent on constitutional derangement, culminating in a kind of inflammatory paroxysm assumed to be connected with excess of lactic acid. Unlike ordinary synovitis, the constitutional disturbance in this case is primary instead of secondary; and though a joint, when attacked, may display signs of severe and acute inflammation, yet these signs will often disappear with extraordinary rapidity, whilst other articulations become as suddenly affected. Acute rheumatism, therefore, being essentially a constitutional malady, falls naturally to the care of the physician, and its description must be sought for in works on medicine.

Chronic osteo-arthritis; chronic rheumatic arthritis; rheumatic gout.—The synovial membranes, as well as the other structures entering into the composition of a joint, are liable to a chronic affection, which has long been practically recognized, though varying names have been assigned to it at different times, or according to the class of joints which it happens to implicate. The term *nodosity of the joints* was the one proposed by Dr. Haygarth, whose attention was attracted to the hard swellings presented by the smaller articulations of the hands and feet, which at the present day more commonly receive the appellation of *rheumatic gout*. When the larger joints, such as the shoulder, the elbow, or the knee, are implicated, the disease is often termed *chronic rheumatism;* whilst a similar affection of the hip has been described by some authors as the *morbus coxæ senilis*. Dr. Adams, of Dublin, however, in his valuable work on the subject, has arranged and classified the varieties of the affection, and proposed the term *chronic rheumatic arthritis*, for which, however, the name *chronic osteo-arthritis* has lately been substituted in the official Nomenclature of Diseases. It will be seen that the disease implicates other tissues besides the synovial membrane; and, indeed, the changes which occur in the bones in these cases are so specially marked, that Mr. Barwell considers the morbid action to be in reality a rheumatic osteitis. The first obvious symptoms during life, however, are those in relation with the synovial membrane, and the earliest traces of disease after death have been found to be connected with the same tissue. Cruveilhier, Dr. Robert Adams, and Sir Benjamin Brodie coincide in the opinion that a chronic inflammation of the synovial membrane is the earliest local result as far as the articulation is concerned; and I have therefore thought it best to notice the affection in the present section.

Chronic rheumatism is met with in two distinct conditions; as a palpably constitutional affection, implicating a multiplicity of joints, and either succeeding to rheumatic fever or following exposure to the usual exciting causes of rheumatism; and, secondly, as a local affection attributed to over-exertion, or injury, or arising without any assignable cause. The two sexes are, perhaps, nearly equally liable to be attacked; but Dr. Adams is of opinion that the larger joints, especially the hip, are more frequently affected in males, whilst females are more subject to the disease in the smaller articulations, such as those of the fingers; a fact which was originally pointed out by Dr. Haygarth. Though usually met with after middle age, chronic rheumatism is by no means confined to elderly people, for it has been seen in patients under the age of twenty, affecting simultaneously a considerable number of joints. Nor is it confined to any special rank; for though it prevails extensively among the laboring poor, it is also frequently met with in the wealthier classes, among those who have led indolent and luxurious lives, and in whom it is apt to assume a more decidedly gouty character. Though chronic rheumatism materially diminishes the *comfort*, it does not appear to shorten the actual *duration* of life, at least in those whose means allow them to be supplied with all requisite appliances; the very poor, however, are exposed to accidental or extraneous maladies, from the helpless condition to which they are reduced, and so with them the chances of life are diminished. When once the disease has become established, its tendency is to progress, slowly but surely, until the joints affected become ultimately disorganized to a greater or less extent; sometimes the affection remains quiescent, or stationary, for an indefinite period; but very seldom indeed can anything like a cure be anticipated, and then only when the case has been recognized and the treatment commenced before the disease had made much progress.

As far as the local affection is concerned, if we have an opportunity of examining the joint at a very early stage of the disease, we find redness of the synovial membrane, which becomes thickened and fibrous, whilst its fringe-like processes are much developed, and more vascular than usual, the internal surface of the capsule presenting somewhat of the appearance of a villous mucous membrane. There is also effusion of a moderate amount of fluid within the joint. At a later period, the fluid is absorbed; but the ligaments, which had been distended by the effusion, recover themselves but slowly, laying the foundation, perhaps, of the partial or even complete dislocations which are occasionally produced subsequently by the spasmodic muscular contractions which are apt to occur in certain stages of the disease. The capsules become very considerably thickened, and sometimes a bony deposit may be met with in their substance; in the interior of the joint, too, there may be found one or more of those foreign or extraneous bodies which are noticed separately in this essay under the head of loose cartilages. The articular cartilages by this time are probably affected; at certain points they assume a yellowish hue, and become fibrous. As the disease progresses, they are destroyed to a greater or less extent; sometimes presenting patches of dense bone, which are smooth and glistening; whilst at other times the cartilaginous tissue disappears entirely. and in its place we find a compact ivory-like bony material, which soon becomes highly polished under the influence of the attrition to which it is subjected, or is marked with linear furrows, resulting from the increased wear to which it is exposed in certain situations in the movements of extension and flexion. In the hip-joint, the round ligament, and in the shoulder the tendon of the long head of the biceps, or the glenoid ligament, will often be removed by the process of absorption. The proper osseous structure becomes condensed beneath the articular surfaces, and bony vegetations are thrown out around them, forming buttresses which interfere with the movements of the joints by their mutual apposition. The shape of the articular surfaces is altered; the globular heads of the femur and humerus are flattened, and. as it were, crushed, and the cavities for their reception exhibit a corresponding change resulting in varying amounts of deformity. These alterations have sometimes been mistaken for fracture of the neck of the humerus, or of the cervix femoris, in which bony union had taken place. It may be mentioned, too, that the abnormal condition is not always confined to the articular extremities, but may involve the shaft, or even the entire bone.

The general symptoms in these cases present no very special character. In some instances, as Sir Benjamin Brodie remarks, the disease appears to be connected with over-indulgence in animal food, and the patient experiences some of the usual effects of dyspepsia, such as a tendency to acidity and flatulence. In other cases, and especially, perhaps, where the larger joints are implicated singly, no particular constitutional derangement can be detected, and, indeed, it is remarkable to how slight an extent the general health is affected by the great amount of topical mischief which may have occurred.

The local symptoms are the most characteristic, and consist essentially of *pain, enlargement and ultimate deformity of the joint, rigidity or stiffness*, and a peculiar *crackling noise*. The pain experienced is principally felt at night-time, or when the joint is set in motion after a period of rest. The amount of pain, which is usually of an aching character, is far less than might be expected from the amount of structural alteration which occurs, and very different from that experienced in other affections of the articular ends of the bone implicating the joints. When only a single articulation is involved, the general suffering is not great, and the patient's condition is very tolerable; even when several joints are attacked, the amount of pain experienced may be only trifling, though it may become aggravated, especially under the influence of cold and humidity, and of atmospheric changes, to such an extent as to render rest almost impossible. In the earliest stages, when the enlargement depends probably on increased effusion into the synovial membrane or the bursæ in its neighborhood, the swelling is soft, and fluctuation may sometimes be detected. At a later period the swelling becomes hard, and osseous growths may often be felt connected with the periosteum and extremities of the bones, which lead to alterations in the form of the articular surfaces, and give rise to great and peculiar deformity, varying in the individual joints, but characterized in the smaller ones, such as those of the fingers, by the appearance of irregular knots; whence the term *nodosity of the joints*, proposed by Dr. Haygarth. The accompanying illustrations from a preparation in the Museum of the Middlesex Hospital, show the changes in the shape of the bones, the eburnation of the articular surfaces, the copious deposit on the bones in the neighborhood of the joint-ends, and the numerous additamentary bones which are met with in old cases of osteo-arthritis. The case is related by Mr. De Morgan in vol. xix. of the Pathological Transactions, where also a drawing will be found showing the extraordinary change of shape which had occurred in the upper end of the femur.

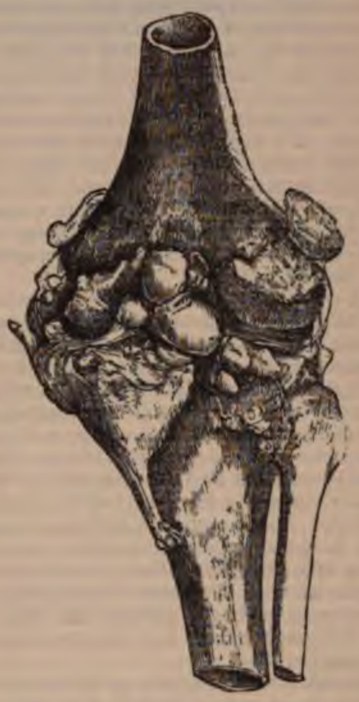
Fig. 664.



Posterior view.

Chronic osteo-arthritis of the knee-joint. (From a preparation in the Museum of the Middlesex Hospital.)

It may be noticed that there is little or no tendency to suppuration in these cases; abscess of the joint rarely, if ever, taking place. The amount of articular rigidity which occurs is peculiarly striking, rendering the affected joints practically useless, and simulating ankylosis, though true ankylosis rarely, if ever, occurs. In the advanced stages of the disease, stiffness or even immobility of the articulations may be present, depending on the deformity which has occurred in the articular surfaces, and on the bony outgrowths which have formed; and where many joints have been affected, the unhappy patient may be confined to his bed in a state of utter helplessness. Though the muscles are not immediately implicated in the rheumatic affection, at some period of the disease, probably when the bone itself begins to suffer, painful spasms are apt to occur, contributing materially to the discomfort of the patient, and giving rise in some cases to the partial or complete luxations which are occasionally met with. When the joints have become rigid and practically useless, the muscles in the neighborhood degenerate and waste. The sensation of decided crackling experienced in the movements of the joint is evident both to the patient and to the surgeon, and is usually most marked when the articulation is first used after repose; it is especially noticed, therefore, in the morning. It depends upon the mutual attrition of the altered articular surfaces, and may be detected in most of the joints, but especially in the hip, and only disappears when complete rigidity has supervened.

[A distinction is made by some writers between chronic rheumatic arthritis and arthritis deformans.[1] The two varieties frequently shade into each other, but a clinical distinction is usually quite marked between that form which is accompanied by stiffness without deformity, and that where the alteration of the shape of the joint is manifest and characteristic. The former is usually the result of a subacute articular inflammation similar to that seen in gonorrhœal rheumatism, the sequela of acute rheumatism or originating spontaneously. The latter is the common affection seen in old people, and causing the deformed hands and crippled fingers frequent in them.

Remak and Benedikt regard this condition as the result of irritation of the spinal cord and sympathetic, akin to that observed in locomotor ataxia. A case of arthritis deformans has been reported where changes either primary or secondary were found in the cord and the trunks of the spinal nerves at the intervertebral foramina. The disease when attacking the smaller joints is usually symmetrical, according to Budd, Romberg, and Charcot, which would point to a central origin; it cannot, however, be considered that the existence of an "arthritis myelitica" is demonstrated, as claimed by Remak.

The articular ends of the bone are distorted by the absorption of the bone at places, and the formation of bony projections at others. The former change is due to an inflammatory subchondral wasting, and the latter to a cell-development from the cartilage, with subsequent ossification. The tendons in the neighborhood of the joint are sometimes ossified, and the adjacent muscles suffer atrophy.[1]]

Treatment.—Dr. Haygarth, to whom we are indebted for our earliest notices of this disease, lamented the scanty means of treatment which he could suggest, and hoped, when time had been afforded for investigation by the profession, that fresh and more successful curative measures might be discovered. These hopes, however, have as yet been only partially realized; and in the advanced stages of the malady, when the joint has been essentially disorganized, we can scarcely anticipate much improvement. Our treatment, therefore, to be of real service, must be adopted at the commencement of the affection; at a later period we can but hope to mitigate the symptoms, to relieve the sufferings, and, at best, to retard the progress of the disease. In the early stage, when inflammatory symptoms are present, and any movement of the joint is attended with acute pain, it may be necessary to employ cupping or leeches, to keep the part at rest, and support it by means of bandages or splints. Care, however, must be taken not to prolong too far the period of immobility, for in these cases especially, want of exercise of the joint has ere long a deleterious influence on its structure. When the acuter symptoms subside, therefore, and rigidity increases, the patient should be encouraged to use the limb, to promote polishing and induration of the articular surfaces. Warmth and friction to the part are usually grateful. Flannel should be worn; and shampooing may be employed, or local douches or hot-air baths had recourse to. At certain stages of the affection counter-irritation may be used in the form of blisters or of painting with iodine; and in the nodosities of the fingers, the local application of a solution of iodide of potassium under oiled silk is sometimes of service; or cod-liver oil may be applied externally, as recommended by Sir Benjamin Brodie.

[In certain cases of chronic rheumatic arthritis, the persistent employment of frictions, rubbing with oil, and vapor-baths, continuously carried out, appears to be of benefit.[2] Remak, Althaus, and others advise the use of the ascending continuous current, which in their hands has produced relief or improvement.[3] Volk-

mann[1] reports success in treating some cases by forcible straightening under chloroform, followed by the immediate application of fixed apparatus (plaster-of-Paris bandages), preceded, when necessary, by tenotomy, and followed by massage and warm baths.]

The general or constitutional treatment must be adapted to the individual case, and to the stage at which the disorder has arrived. Where any gouty element exists, where dyspeptic symptoms are present, and the case appears connected with too full a habit, great attention to the diet becomes of importance; stimulants should be abstained from; sugar, fruits, and raw vegetables avoided; and a moderate quantity of potash or magnesia be administered three or four hours after each principal meal. In other cases, however, the system appears impoverished rather than too full, and here it may be necessary to employ a better and more nutritious diet. In the earlier stages of subacute inflammation, it may be advisable to give a few alterative doses of blue-pill, combined, perhaps, with acetous extract of colchicum, and to administer Gregory's powder at night-time, with an active aperient at regular intervals. Perspiration should be encouraged, too, by the use of the Turkish or hot-air bath, or by taking Dover's powder, or other medicines to act upon the skin. When the urine is clear, Mr. William Adams recommends the use of sulphur externally and internally, and also the free use of dilute phosphoric acid. At a later period, the iodide of potassium may be administered and continued for several weeks at a time, if it appears to suit the patient; for its action in these cases is somewhat uncertain. Various stimulating internal medicines may now be tried, such as turpentine or guaiacum; or cod-liver oil may be administered internally as well as externally; opiates also are usually of service for the purpose of procuring rest. Warm clothing should be used; and, where circumstances admit, residence in a warm climate during the winter months materially increases the comfort of the patient. Warm bathing is usually attended with relief; and if practicable, recourse should be had to the mineral springs, such as those of Bath or Buxton in this country, the hot sulphur baths of Luchon in the Pyrenees, Aix-la-Chapelle, Vichy, Ems, Wiesbaden, or Carlsbad on the Continent, [the Hot Springs of Arkansas.]

Gouty synovitis.—The gouty diathesis presents some points of resemblance to the rheumatic; in fact the chronic form of alteration of the joints just described is often termed rheumatic gout. The speciality of the gouty inflammation, however, consists in the sudden or "explosive" appearance of uric acid in the part affected, giving rise to more or less local disturbance. Gouty inflammation of the joints occurs in an acute or in a more chronic form. The acute form of gout requires no description here, as it is essentially a medical complaint, and is amply treated of in medical works. Where gout has assumed a chronic form, however, the local affection may predominate over the constitutional, and such cases may at times fall under the care of the surgeon; they require, therefore, to be briefly noticed.

When gout first attacks a patient, the joint usually recovers its original mobility as the "fit" passes off; but when repeated attacks have occurred, the restoration becomes more and more imperfect, and at last the articulation loses entirely its capacity for motion. Opportunities of examining the joint at an early stage are not common; but Dr. Garrod is of opinion that gouty inflammation is *invariably* accompanied by deposition of its peculiar salt. Unquestionably, as the disease advances, a deposit of the white, chalky-looking urate of soda takes place, in the substance of the ligaments and in the surrounding areolar tissue, as well as in the neighboring muscles; or it may occur in the interior of the joint, thickening the synovial fluid, and studding the synovial membrane with small white masses: or in the substance of the articular cartilages, in the form of white spots, resulting from the presence of the crystalline salt in the hyaline structure; or, finally, the urate may be deposited in the bone and in the periosteum. Resulting from this deposit we may expect to find, sooner or later, the tissues themselves undergoing changes; the synovial membrane will be thickened and vascular; the ligaments and areolar tissue condensed; and the cartilages subsequently become softened and are removed, so that the articular surfaces of the bones are exposed and altered.

Whenever a joint is subjected to protracted attacks of chronic gout, it is certain to be permanently injured, either by becoming so rigid that its functions are practically destroyed, or from the formation of *chalk-stones* around it. Chalk-stones—or *tophi*, as they are sometimes termed, from a Hebrew word signifying *concretion*—vary much in their consistence; they may be soft and semi-fluid, or hard as the chalk from which they derive their name. Under the microscope they present bunches of needle-like crystals of urate of soda; and chemically they are

---

[[1] Billroth and Pitha, Handbuch der Allg. Chir.]

composed of that salt, united with a certain amount of animal or earthy matter. A concretion taken from the metacarpus was found by Lehmann to contain :—

Urate of soda	52.12
Urate of lime	1.25
Chloride of sodium	9.84
Phosphate of lime	4.32
Cellular tissue	28.49
Water, loss, etc.	3.98
	100.00

Chalk-stones are generally found in the smaller articulations of the hands and feet. They form protuberances, distorting and crippling the articulation, which approach the surface, till the skin over them is thinned, and allows their white color to become visible. Sir T. Watson relates the case of a gentleman who was in the habit, when at cards, of scoring the game on the table with his chalky knuckles. It may be mentioned, as sometimes facilitating our diagnosis, that there is another situation in which deposits of urate of soda are even more commonly visible than in connection with the joints, namely, in the cartilage of the external ear, in the form of little pearl-like bodies, varying in size from a split-pea to a mere white point, and situated usually about the fold of the helix. Out of seventeen cases in which Dr. Garrod detected gouty concretions, in seven they existed in the ears *alone*, in nine in the ears *as well as* around the joints, and only in one case were they found in other parts, but *not in the ear*. The gouty deposit, which is at first liquid, becomes harder in time from absorption of its fluid parts, and accumulates in many cases to such an extent as to render the joint completely fixed, whilst the neighboring structures are also inconvenienced by the distension to which they are subjected. The mere presence of the salt in connection with the joint does not appear usually to produce much irritation; after a time, however, inflammatory action, perhaps from a fresh gouty attack, may be set up, the integuments ulcerate, and a discharge, containing the urate of soda mixed with blood-globules, takes place through openings which are often most troublesome to heal. These abscesses, however, it may be mentioned, appear sometimes to act as safety-valves, and their cure is followed by renewed attacks of gout, which had been suspended during the time they remained open. The diagnosis between chronic gouty affections of the joints and the chronic osteo-arthritis already spoken of, is rendered easy when ulceration of the soft parts has occurred, and chalky matter exudes, which can be determined by chemistry to consist of urate of soda. At an earlier period some uncertainty may exist; though the case may be considered gouty, when it comes on after repeated and manifest attacks of gout, and when the gouty diathesis is plainly marked; it may be proved to be so, if a puncture of the swelling with a needle allows of the escape of fluid in which the presence of crystals of the urate of soda is revealed by the microscope: for the existence of this salt forms the specific characteristic of the *gouty* affection, and is never met with in rheumatism or in chronic osteo-arthritis.

Treatment.—As the disease is essentially a constitutional one, the treatment must also be mainly constitutional, and consists in impeding the undue formation of uric acid, as well as in getting rid of the surplus amount of the acid already existing in the blood. For the first purpose the diet has to be carefully attended to; the dyspeptic symptoms relieved as far as possible; the secretions, especially that of the liver, regulated; and the strength of the patient supported in those cases where there is a tendency to loss of tone. To free the blood, we may administer occasionally small doses of colchicum, when the strength of the patient admits of it; but our main efforts are directed to increase the action of the kidneys and skin by means of salines and alkalies. The salines, to be of service in chronic cases of gout, must be given in small doses and very diluted; they should be taken on an empty stomach and some little time before food. [Of the salines, the carbonates of potash and soda are the ones chiefly employed, and lime-water and magnesia; but the drug most recommended of late years is the carbonate of lithia.[1]] The mineral waters, properly selected, offer many advantages for the administration of saline medicines, as well from the state of dilution in which they are found, as from the greater chance of the patient continuing to take them for a sufficient time, while the mind is occupied and the attention diverted by the change of scene and hopeful statements afforded at the various spas. The external use of the waters can also be conveniently and usefully adopted. The spa to be selected must depend to a great extent upon the special characters of the individual case. In some, Carlsbad, Wiesbaden, or Vichy may be recommended; whilst in other cases, Aix-la-Chapelle, Teplitz, Wildbad, and Buxton are more likely to be of service. Where the debility is great, or after a course of other waters has been taken, the ferruginous springs of Schwalbach or of Pyrmont are often beneficial. For those who are prevented from going

---

[[1] Senator, article "Gout," in Ziemssen's Cyclopædia of the Pract. of Medicine.]

to a great distance, or who are desirous of feeling their way and seeing which spring is likely to suit them best, a trial of the carefully prepared factitious mineral waters of the spa at Brighton may at times be deemed advisable, and the Turkish bath is often of much service.

It is, however, for the local mischief that the surgeon may principally expect to be consulted. The local treatment will vary according as it is directed simply to relieve the stiffness and rigidity of the joints, or to alleviate any active inflammatory action which may have been set up, with or without the formation of abscess and production of ulceration. To relieve the stiffness, one topical application has, indeed, been already alluded to, in the form of baths of the mineral waters. Where these cannot be had recourse to, weak alkaline lotions, with iodide of potassium, may be applied to the joint under oiled silk, or, supposing the smaller joints of the fingers to be affected, the whole hand may be wrapped in bandages saturated with water and then enclosed in a waterproof bag during the night. When a certain amount of low or chronic inflammatory action is going on in the ligaments and synovial membranes, small flying blisters are often useful, applied only for a short time, and with tissue-paper between them and the skin; in this particular condition, too, the internal administration of small doses of iodide of potassium is often of use. When acute inflammation occurs, as it may do when a new and severe attack of gout takes place in the seat of a chalkstone, the amount of swelling which ensues may cause the cutis to give way, whilst the cuticle remains entire. It is better in these cases to avoid, if possible, making any incision; for the salt is deposited not simply in the cellular tissue or collected as a mass, but also in the actual substance of the articular cartilages, and cannot, therefore, be expected to be entirely or freely evacuated. Soothing applications are of most service; but it may be remarked, that where an opening occurs naturally, or is made by the surgeon, the serious consequences frequently attendant on wounds of articulations are not to be expected, partly from the disorganization which has occurred, partly also, no doubt, from the unimportant character of the joint which is usually involved. Severe operative measures are not called for in these cases. While the inflammation runs high, poultices and fomentations are of most service; afterwards, gentle pressure may be employed, and the sinuses which are left should not be irritated by probing or by stimulant applications, but allowed gradually to contract and ultimately heal. As already stated, when ulceration has once occurred, the case is almost invariably tedious, and may be rendered more so by too active surgical treatment.

Pyæmic synovitis.—Acute synovitis, frequently leading to suppuration in the joints, is not a very uncommon consequence of purulent or systemic infection, and is met with in phlebitis, after operations, and in connection with certain puerperal conditions, as well as in the progress of fevers, etc. For the description of the general condition giving rise to this complication, its symptoms, and its treatment, the reader is referred to the essay on PYÆMIA. It need only be stated here, that when this pyæmic condition exists, there is always danger of the joints, as well as of other parts of the body, becoming the seat of the local disturbance. Sometimes the attack is marked by the occurrence of violent pain, accompanied or followed by heat, redness, and swelling, affecting one or more of the articulations, which may present distinct fluctuation, provided they are superficially situated. In these cases more or less thin and liquid pus may be found in the interior of the joint, or in some instances, diffused throughout the external areolar tissue. In other cases, however, large deposits of pus may take place in the joint, suddenly or insidiously, unaccompanied by pain, and perhaps unsuspected during life. The number of joints affected may vary considerably. Only one may be attacked, or it may be difficult to find a single articulation which does not present pus when cut into. The inflammatory condition may remain confined to the synovial membrane, but frequently extends to the other structures, which become more or less disorganized. In a case of suppuration of the knee, following thecal abscess of the finger, Dr. Handfield Jones found increased vascularity of the synovial membrane, with villous projections from its surface; whilst the articular cartilage was ulcerated in places, the cartilage-corpuscles containing a greatly increased number of celloid masses in their interior, and the intercellular substance being fibrous, and deprived of its natural consistence.

The *treatment* in these cases is mainly directed to the relief of the constitutional infection, and its principles have been laid down in the essay on PYÆMIA. Locally, when we have reason to suppose that a joint is becoming implicated, it should be maintained in a state of perfect rest upon a splint, and the pain relieved by soothing applications. When suppuration has indubitably occurred within the joint, a free incision for the purpose of evacuating the matter is desirable, and the local treatment already recommended for abscess in the synovial membrane becomes applicable.

[Poly-articular inflammation of the joints, similar to that termed gonorrhœal rheumatism, has been occasionally observed after catheterization, or the introduction of lithotrites, by Velpeau, Civiale, and Bonnet.[1]]

Gonorrhœal synovitis; gonorrhœal rheumatism.—A form of synovial inflammation is occasionally met with in connection with purulent inflammation of the urethra, or even with purulent ophthalmia. This complication appears to have been first described by Sir Benjamin Brodie, and usually passes now under the name of *gonorrhœal rheumatism*, though it differs in several respects from rheumatism, and is not necessarily connected with gonorrhœa. In these cases, during the existence of a urethral discharge, which may depend on gonorrhœa, or arise after the passage of a bougie, inflammation occurs in the synovial membranes of one or more of the joints, more particularly in the knee. Another peculiarity, which was pointed out by Sir Benjamin Brodie, is, that some form of ophthalmia very commonly accompanies or precedes the articular affection, or may alternate with it. All stages of gonorrhœa may present this complication, and usually no material change in the discharge is noticed, though sometimes it declines a little, when the synovial affection shows itself. The articular inflammation may last for a few weeks, or may continue for months or even years. It is very apt to involve one joint after another, and presents a decided disposition to relapse. There is little tendency to suppuration, but sometimes the synovial membrane is thickened, and the movements of the joint permanently interfered with. In some few instances the case is much more severe; the cartilages become involved, and permanent rigidity may be the result.

The immediate cause of this affection is still a matter of dispute. By some it has been considered to be connected with the gouty habit;[2] whilst Mr. Barwell considers it to be "in reality a slower form than ordinary of purulent infection, produced by inflammation of the prostatic veins."[3] He allows, however, that he has "no cases of dissection to prove this position," but the following case, related by Mr. Prichard, certainly seems to favor Mr. Barwell's views.

> A patient in the Bristol Infirmary for gonorrhœa and orchitis, was attacked with feverish symptoms, followed by great pain and swelling in the right knee. In a few days the lower part of the thigh was filled with matter which had escaped from the distended synovial membrane. The limb was subsequently amputated, and the joint found to be completely disorganized.

Treatment.—The local treatment in these cases is much the same as that recommended in ordinary synovitis. So long as acute inflammatory symptoms are present, the usual antiphlogistic measures must be had recourse to, and if the pain is very severe, as is sometimes the case, subcutaneous injections of morphia may be employed; when effusion remains, free blistering should be employed, and "Scott's bandage" applied in those cases where there is thickening about the joint. At a subsequent period, friction, shampooing, local vapor baths, or the use of the mineral waters of Buxton or of Wiesbaden, will probably be of service. The general treatment must also be conducted on the ordinary physiological principles. As the inflammatory excitement passes off, the iodide of potassium, combined with colchicum and opium, may be administered, along with occasional active purgatives; to be followed at a still later period by mild tonics. In the more chronic forms of the disease the greatest benefit will be derived from change of climate, including a residence at the mineral springs recommended for chronic rheumatism, with the use of the waters both internally and externally. The treatment of this affection by keeping bougies in the urethra, or by the administration of cubebs and copaiba, as once recommended, is hardly likely to be often had recourse to in the present day.

Syphilitic synovitis.—The character of the synovial inflammation in some cases is modified by the existence of constitutional syphilis. Occasionally, as Sir Benjamin Brodie remarks, the synovial membranes of one or more joints assume a sluggish form of inflammation in the early stages of secondary syphilis, in connection with papular eruptions. More frequently, perhaps, the joint-affection comes on at a more advanced stage of syphilitic infection, in connection with affections of the bones, and especially of the periosteum. The inflammation in most cases is anything but rapid in its progress or acute in its symptoms, though the nocturnal pains may be severe; and it is readily distinguished by its occurrence during the ex-

---

[2] Johnstone, On the Genito-Urinary Organs, p. 317.

[3] On Diseases of the Joints, p. 101.

istence of other and characteristic symptoms of venereal blood-poisoning. Its constitutional origin is also marked by its tendency to affect more than one joint. The general treatment is naturally directed to the cure of the syphilitic infection. Mercury may be used in the form of fumigations, in conjunction with the vapor-bath, in many cases where it cannot safely be taken internally. The iodide of potassium, in moderate, or, if need be, in very large doses (forty to sixty grains a day, combined with sarsaparilla, or other medicines that tend to strengthen the patient, is often of the greatest benefit. Locally leeches are seldom required. Soothing applications may be had recourse to if the pain is severe, but rest of the limb by means of splints, and mild counter-irritation, are the remedies most frequently of service.

[The syphilitic affections of the joints are either directly due to the presence of a tertiary deposit in the vicinity, causing an effusion in the joint, or they are simply a synovitis occurring in a syphilitic person—in which latter case they scarcely differ from the so-called "scrofulous" or rheumatic synovitis. G. Bouilly,[1] Cottin,[2] and Mollière[3] report cases cured by the administration of iodide of potassium in large doses. Volkmann[4] mentions a poly-articular synovitis apparently arising from syphilitic poison, and this form is more common than caries.[5]]

"*Loose Cartilages*" *in Joints.*

We occasionally find in some of the articulations small movable bodies, which may be quite free, or still attached to the walls of the joint by narrow pedicles, and to which the name of "loose cartilages" has been given. These bodies, which are usually met with in adults rather than at an earlier period of life, vary in their structure; some are comparatively soft, of a yellowish color, and resemble masses of fibrin; in other cases, they are hard and glistening, rather white than yellow, and evidently composed of cartilage or fibro-cartilage, both on the surface and in their interior; frequently, too, they are partially, or sometimes almost completely, converted into bone. In many cases we find only one such body in a single joint, but it is by no means uncommon for two or three to be present, and occasionally they are met with in much higher numbers. Morgagni, for instance, discovered twenty-five smooth and polished globular bodies in the left knee of a woman who died of apoplexy. They vary considerably in size, being sometimes no larger than a barleycorn, whilst in other cases they may nearly equal the patella itself in their dimensions. When small they are usually round or oval; when of considerable size they may be elongated, flattened, or tuberous. The most common situation for these "loose cartilages" is the knee; but they are not confined to that joint; they have also been discovered in the other articulations, including even the hip, which was long supposed to be exempt from them.[1]

"Loose cartilages," in many cases, at any rate, appear to take their origin from the small irregular projections which naturally exist in connection with the "vascular processes" of the synovial membrane. In certain abnormal conditions these processes increase in size and solidity, and may ultimately become detached from their connections, so as to form separate bodies, which are perfectly

[[5] Weil, Centralblatt f. Chirurgie, No. 21, 1877.]

[1] See Archives générales de Médecine, tome xii. (1846), p. 363. [A case reported by Foucher, Nouveau Dict. de Med. et de Chir., vol. iii., p. 355; Nicaise (Diagnostique des Maladies de la Hanche, p. 105) mentions a case reported by Cruveilhier, where 15 free, small cartilaginous bodies were found in the hip-joint of a girl who had suffered for 10 years with occasional pains and stiffness in the hip.]

free in the joint, or they may still remain connected with the parietes by an elongated pedicle. They are composed of "connective tissue with elongated nuclei, and coated with epithelium, and, though not always, contain a variable number of scattered fat- and true cartilage-cells; and they are not developed externally to the synovial membrane, but from an outgrowth of that membrane itself."[1] Occasionally we find imperfectly-formed bone in the substance of the masses, derived probably from a further stage of conversion of the cartilage, or they may be bony throughout. According to Dr. R. Adams, these foreign bodies, which may be supposed usually to take their origin from the synovial membrane, are especially connected with the condition constituting *chronic osteo-arthritis*, though it is not denied that they are seen in articulations which present no trace of that disease. It is probable, however, that the detached bodies found in joints may have more than one origin; occasionally, perhaps, they may result from a blood-clot which has lost its coloring matter, and now consists only of fibrin; and in many instances they can be traced to an accident by which, probably, a portion of cartilage or fibro-cartilage has been detached, and which may, after a time, become smooth from long-continued friction.

In support of this view, Mr. Brodhurst[2] relates an interesting case in which, six weeks after the accident, he removed from the knee-joint a "loose cartilage," which proved to be the anterior portion of the internal semilunar cartilage, retaining in every respect its normal appearance.

A "loose cartilage" may exist in the joint for a length of time without producing sufficient disturbance to attract the attention of the patient, or to make him think that he is subject to anything more serious than occasional rheumatic twinges. At last, however, in some movement of the joint, the foreign body slips between the articular ends of the bones, and then a violent and sudden pain is experienced, with inability to use the limb, which remains fixed in the position which it may have happened to assume at the time. The pain continues until the "cartilage" is dislodged by some means, when the immediate symptoms at once subside, though they are often followed by inflammation of the synovial membrane, accompanied with effusion. The character of the suffering in these cases is peculiar, being often sufficient to make the patient fall, or even to occasion syncope, and is probably due to the sudden stretching of the ligaments caused, in the case of the knee-joint, by the tibia and femur being forcibly separated when the loose cartilage gets between their articular ends during flexion, and is accidentally caught during extension, before it has time to slip aside. The attention of the surgeon is now called to the part, and, on careful examination, he may succeed in discovering a firm extraneous body in the joint, which slips beneath the finger, to be lost beneath the patella or the tendinous structures above or below that bone. When the symptoms described have once occurred, they may be repeated at varying intervals; in some cases recurring on the slightest movement, and even during sleep, whilst in others they may be kept in check so as to give rise to but little practical inconvenience. If the attacks are frequent, however, the joint suffers sooner or later; the ligaments become relaxed, disease extends to the harder tissues, and the articulation is permanently injured. Many of the symptoms produced by a "loose cartilage," it may be mentioned, are occasionally met with as the result of partial dislocation of a fibro-cartilage in the knee, as well as, more rarely, in the articulation of the lower jaw, constituting what Mr. Paget terms *locked joint*.[1] A description of this condition in the knee will be found in the essay on INJURIES OF THE LOWER EXTREMITY, Vol. I., p. 979.

The treatment to be adopted may be either palliative or radical. In the first place, however, any inflammation which may be present must be subdued, and any dropsical effusion got rid of by blisters or other appropriate remedies. When this has been done, a well-fitting elastic bandage, or still better, a back splint, which will prevent the joint from being flexed, should be constantly worn, whilst the loose cartilage may be fixed (by means of pads or strapping) to some part of the synovial membrane, in the hope that absorption may ultimately take place, as will sometimes happen. In many cases this treatment is sufficient; but in some, inconvenience is still experienced to such an extent as to suggest further operative measures. When such is the case, the extraneous substance may be removed from the cavity of the joint, either by direct or by subcutaneous incision. Both these operations, however, are attended with a very decided amount of risk, and should only be performed when the palliative treatment has been fully tried and *failed*, and the foreign body continues to give rise to active mischief. The foreign body, too, should be clearly movable, and capable of being brought to a part of the joint in which it is easily accessible. The patient should be prepared for the operation, both by appropriate diet and regimen, and also by the limb being kept perfectly at rest for a few days. The loose cartilage is then guided to that part of the joint where it is most superficial, and fixed securely, so that it may not slip out of the way during the operation. If the *direct* operation is the one adopted, the parts over the foreign body are now divided, and a sufficient opening made in the synovial membrane to allow the cartilage to be pressed out of the wound, without any unnecessary manipulation or disturbance of the joint. The edges are then accurately brought together by sutures or strips of plaster, and the limb kept at perfect rest on a splint; constant cold may also be applied to the joint, to prevent, if possible, the occurrence of inflammatory symptoms. In the *subcutaneous* operation, the cartilage having been securely fixed as before, a tolerably long tenotomy knife is introduced through the skin, at some few lines distance, and passed through the cellular tissue so as to make a subcutaneous incision into the joint. Great care must be taken in dividing the synovial membrane, that the foreign body does not slip aside, for which purpose it is better for the operator to secure it himself with one hand, whilst he makes the incision with the other. The loose cartilage is then pressed either *into* the aperture in the synovial membrane (as recommended by Mr. Square), or *through* it into the subcutaneous areolar tissue, and retained in either position by appropriate means, in the expectation of its becoming ultimately absorbed.

---

[1] See note to Kölliker's Manual of Human Histology, vol. i., p. 328.

[2] St. George's Hospital Reports, vol. ii., p. 142.

[1] British Medical Journal, January 5, 1867.

Sir Benjamin Brodie states, in his work on the joints, that his experience does not enable him to determine which of these operations (the direct or subcutaneous), is to be preferred. According to M. Larrey, who refers to 167 published cases of removal of loose cartilages by operation, out of 131 cases in which the old or direct method was employed, 98 were successful, 5 doubtful, and 28 died; whilst of 39 indirect operations, 19 were successful, 15 failed, and 5 died. From this it would appear, as M. Larrey states, that extraction by either method is attended with decided danger; but that in the *direct* operation, the risk to life is greater than in the *subcutaneous*; while, on the other hand, in the subcutaneous operation there is increased difficulty, and consequently less chance of success. On account of the difficulty which is experienced in getting the cartilage out of the joint into the cellular tissue without an undesirable amount of manipulation, Mr. Syme recommends another method, by which, he says, he generally succeeds without risk. This consists in "making a free subcutaneous incision through the synovial membrane and cartilage, and applying a blister over the part where it is retained."

[In contrast to these figures of M. Larrey, Mr. Morgan cites 18 cases where the knee-joint was opened under antiseptic precautions, with complete success in all. The operation was undertaken in most of these cases for the removal of a foreign body.[1] This method is therefore destined to take the place of all other older procedures.

Verneuil[2] reports 53 cases of successful removal according to the subcutaneous method, 27 failures, and 10 deaths. Removal of foreign bodies by direct incision with antiseptic precautions has been successful 25 times, and there have been 2 deaths resulting from imperfect antiseptic measures. Berthenson collected 162 operations done without antiseptic precautions: 130 were removals of loose cartilages by a direct incision; there were 20 deaths: 32 by indirect incision with no deaths, but 10 were failures.[3]]

DISEASES OF THE ARTICULAR EXTREMITIES OF THE BONES.

The diseases of the joints which originate in the articular extremities of the bones are next in importance and in frequency to those which commence in the synovial membrane. It will not be necessary, however, to enter much into detail in treating of them here, as the morbid processes have been already described in a preceding essay, on DISEASES OF THE BONES. A brief notice of these affections in their relation to the joints will therefore be sufficient.

Simple inflammation of the articular ends of the bones, and its consequences.—The articular extremities of bones are liable to attacks of simple inflammation, which may result from injury, or depend on other causes. The changes which take place resemble those which result from inflammation of other tissues, when allowance is made for physical differences of structure. In favorable cases restoration to a healthy condition occurs, or the inflammatory products may give rise to

---

[[1] St. George's Hospital Reports, vol. ix., 77–78.]

[[2] Revue des Sciences Méd., Jan. 15, 1880.]

[[3] Volkmann, Billroth, and Pitha, Handbuch d. Chirurgie; Brit. Med. Journ., Feb. 12, 1877.]

deposition of increased ossific material, leading to hardening and increased weight or size of the part. In less favorable cases suppuration takes place, which may be circumscribed, forming a *local abscess* in the articular extremity, or diffused in the cancellous tissue, as in *osteo-myelitis*.

Local abscess of bone is usually found in the head of the tibia, and, as a general rule, is recognized and remedied before the articulation is affected. If not, the synovial membrane becomes inflamed from time to time; and if the original mischief is still allowed to remain, the matter may at last make its way into the joint, giving rise to suppuration in that cavity. For a detailed description of the symptoms and treatment of *local abscess in the cancellous tissue*, as well as of *osteo-myelitis* (which may in like manner lead to a discharge of pus into the nearest joint-cavity), the reader is referred to the essay above mentioned.

The inflammation may lead to the death of the whole or a part of the articular extremity, constituting *necrosis*. If the dead portion is limited in its extent and situated near the surface, the articulation may escape with little or no damage, and the sequestrum separate or be removed by operation. Sometimes the necrosis is deep-seated, presenting then many points of resemblance with local abscess of bone, like which it may lead to destructive inflammation of the joint. In some of these cases the true state of things is only recognized when death or amputation allows the parts to be dissected; in others, however, a similar operation to that required for local abscess can be performed, the dead bone is removed, the pent-up matter evacuated, and the joint is saved. Sometimes the whole or the greater part of the head of the bone dies, giving rise, of course, to rapid destruction of the joint. As no hope can exist of saving the joint in such cases, its removal, when practicable, becomes the only course to be pursued. In early life, it should be noticed that the *epiphysis* may be separated from the shaft of the bone, and lie loose in the joint, as the result either of acute or chronic disease. In such cases removal of the detached epiphysis will probably often be sufficient, should the true state of the case be detected, which may sometimes happen, though there are no very positive symptoms to distinguish this from other forms of death of the articular extremity. In necrosis affecting the very small joints, such as those of the fingers and toes, the amount of constitutional disturbance involved is so slight that we may wait, if we think it expedient, for the natural separation of the parts. In this way a sufficiently useful thumb or great toe may be preserved, the superficial position of the articulation facilitating the removal of the dead bone.

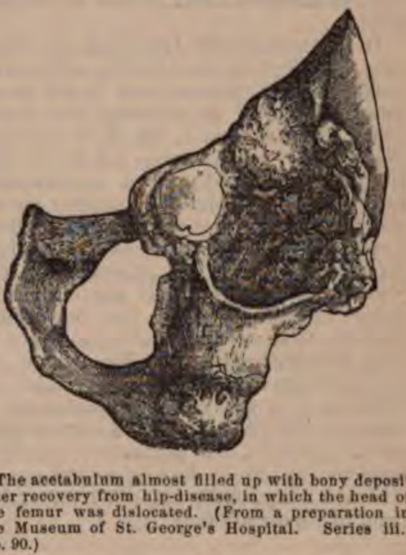
Finally, instead of death occurring in obvious masses, the inflammation may lead to a molecular destruction and removal of the osseous tissue, by a process analogous to ulceration, which is termed *caries*. Caries of bone in the vicinity of joints may arise from simple inflammation; it occurs, however, so much more commonly as the result of a low form of inflammation usually described as *scrofulous*, that it is convenient, practically, to defer its consideration, or to merge it in the description of the latter form of disease, to which we now proceed.

Scrofulous inflammation of the articular ends of the bones. — The pathological changes involved in this action, so far as the bone is concerned, are described in the essay on DISEASES OF THE BONES; they need not be recapitulated here. Suffice it to say, that we find the affected bone more vascular than natural (at least at first), then light and oily, as well as unusually soft, so as to admit of being cut with a knife, the cancelli being dilated and filled with a jelly-like substance. This form of inflammation is much disposed to lead to caries. Caries, when affecting the articular extremities of the long bones or the cuboid bones, such as those of the tarsus and carpus, commences frequently in separate points of the cancellous tissue, which gradually extend, and so approach the surface. At last the periosteum itself is reached, and implicated; it becomes detached from the osseous substance beneath, which is left rough and worm-eaten on the surface, bleeding freely, and giving exit to a foul discharge, in which are contained particles of disintegrated bone. The soft parts around share in the diseased action. Serum and lymph are effused into the neighboring areolar tissue, giving rise to a characteristic firm and elastic swelling; at a later period suppuration occurs, and the tissues are traversed by sinuses.

When the disease is situated sufficiently near a joint, the articular cartilages in the immediate vicinity of the inflamed bone become affected; their nutrient supply, as far as the osteal vessels are concerned, is interfered with; their adhesion to the bone is impaired, and they become fibrous and ulcerate, the change commencing usually on their deeper or attached surface; or portions of them may become detached, and ultimately be found loose within the joint. The synovial membrane participates in the inflammation, which may either spread to it from the diseased cartilages, or may affect it more directly by extension from the periosteum to that part of the synovial capsule which invests the bone to a certain extent before it becomes united with the cartilage and perichondrium. It may be remarked that the affection of the articular ends of the bones sometimes assumes a peculiar form, which has received the name of "*spotted ulceration*," but which is probably a variety of the strumous disease. When this is the case, several pits or depressions, containing a curdy matter, are found in the articular surfaces, the cartilages presenting a series of defined orifices, corresponding to the pits in the bone, their intervening structure remaining frequently unaltered. The diseased action, which has been supposed hitherto to be confined to one side of the joint, now becomes diffused; the inflamed synovial membrane goes through the series of changes which have already been described under the head of synovitis; the articular cartilages on the opposite side of the joint become affected, they speedily ulcerate, and the cancellous structure of the bone on which they rest is exposed. The disease gives rise to the formation of matter within the joint; but suppuration, it has already been stated, takes place likewise in the contiguous soft parts. As the case progresses, the matter makes its way to the surface, it may be directly, in the immediate neighborhood of the joint, or forming tortuous sinuses, which open at a considerable distance, and give exit to a profuse discharge. When the long bones are affected, partial or incomplete luxations are apt to take place during the later stages of the malady. The disease may continue to progress till life ceases or the joint is removed; but sometimes, after dislocation has occurred, a reparative process takes place, healthy granulations arise in the bone, the synovial membrane goes through the changes tending to recovery, which have already been described, the discharge diminishes and ceases, anchylosis takes place, and the patient is left with a limb the utility of which varies much in different cases.

Scrofulous disease of the joints, commencing in the bones, as well as in the soft structures, is frequently met with in children of strumous habit, especially in those who have never thoroughly recovered from the depressing effects of some of the ailments to which they are subject. At the Hospital for Sick Children I was able, very often, to trace the attack to the weakened state of health which had remained after scarlatina or measles. In early life the disease may affect indifferently the extremities of the long bones or the cuboidal bones; but when it commences after puberty, which is sometimes the case, it shows a decided preference for the carpal or tarsal bones. The disease is very insidious in its earlier stages, occasioning little pain or inconvenience; in children, the first thing which attracts the attention of the patient in most cases is "limping" when the joints affected are situated in the lower extremity, or unwillingness to use the arm when the upper limb is implicated. It is now noticed too, perhaps, that the child selects that position which will throw least stress upon some particular joint, or that he flinches when that joint is moved or pressed upon; and that the nights are somewhat restless. At this time the little swelling which exists is mainly situated over one of the bones which enters into the composition of the articulation. As the disease advances, the joint itself becomes more decidedly implicated; it is rigid, and more or less flexed according to the care with which it has been treated; the swelling increases, and now takes more decidedly the shape of the synovial membrane, and there is usually effusion of serum and lymph into the areolar tissue over the affected bone, distending the skin, and producing a "white swelling." If the case is neglected, painful startings of the limb begin to show themselves, aggravated at night-time, and causing the child to cry out in his sleep, or to wake up with a shriek of pain. When this occurs, it shows that the articular surface of the bone is affected, and beginning to be laid bare to the joint; the "starting" becomes specially marked, too, when inflammation has extended to the opposite bone, and when, consequently, the two inflamed and sensitive osseous surfaces are subjected to mutual pressure by spasmodic

Fig. 666.



The acetabulum almost filled up with bony deposit after recovery from hip-disease, in which the head of the femur was dislocated. (From a preparation in the Museum of St. George's Hospital. Series iii., No. 90.)

contraction of the muscles. This muscular spasm is originally induced by the osteal disease; eventually, however, it reacts upon that disease, which it aggravates by the forced and violent apposition in which it maintains the inflamed surfaces. Hence the great relief to suffering so often experienced when displacement of the bones take place, under the influence of the morbid muscular contraction, after the ligaments and other retaining structures have become weakened. When this occurs, the mutual pressure of the inflamed bone-surfaces ceases, and from this period a curative process is often dated. Before this happens, however, matter has in all probability formed in or around the joint, and sinuses are produced, taking various directions in accordance with the anatomical arrangement of the part. If a probe is introduced, carious bone can sometimes be felt, but not always, in consequence of the irregular course which the sinuses often take. The integuments around the wounds are thin and discolored, the discharge copious, watery, and unhealthy. The general health by this time usually shows strong signs of breaking up, the child becomes emaciated, hectic manifests itself, profuse night-sweats occur, and, unless relief is afforded, some vital organ becomes implicated, leading to the death of the patient.

[A number of surgical writers claim that tumor albus always is primarily an epiphyseal osteitis. Volkmann goes so far as to state that fungous disease of the joint in children never begins as a synovitis.

It is undoubtedly true that the bony origin of joint diseases is frequently overlooked, and it appears that in the bone, more frequently in children, the initial lesion is to be found, but it is also undoubtedly true that cases not to be distinguished clinically from commencing fungous arthritis, have at autopsy shown nothing except the changes resulting from a synovitis.[1] It is at present impossible to classify accurately the diseases of the joints according to their anatomical lesions; enough however has been done recently to show the great importance of this, both for prognosis and treatment, for it is probable that the course is essentially different in typical cases of epiphyseal or osteo-myelitic disease, and in chronic periosteal, synovial, and periarthritic inflammations, affections having symptoms in common and usually classified under the head of tumor albus.[2]]

Prognosis.—The prospect of a successful issue to the case depends greatly on the treatment being commenced at a very early period, before the joint has become seriously implicated. It is most desirable, therefore, that any expression of pain or tenderness about a joint, or any hesitation in the manner in which it is used, should be at once attended to, and a careful examination made by a competent surgeon. In the wealthier classes this is usually done, and the progress of the case at this period can almost invariably be arrested, and a tolerably perfect cure ensured. Even when the disease has arrived at a more advanced stage, when the joint has become implicated, and suppuration has taken place, care and perseverance on the part of surgeon and patient will usually be rewarded ultimately by success; for these cases occur for the most part in early life, and "in children the plastic powers of nature are so great that recovery may take place, when in the adult any such hope can scarcely exist."[1] These observations, however, apply principally to the wealthier classes; for amongst the poor, who are struggling for their daily bread, early symptoms are generally unnoticed, and the disease has advanced to a great extent before surgical aid is invoked. Even if admitted into hospital, the patient can seldom be kept there long enough for complete recovery; moreover, the general health is apt to suffer, after a time, from the necessarily impure air of a sick-ward, and so the patient returns home, to be again exposed to the imperfect nutrition, the confined air, and the want of rest as well as of necessary comforts and appliances, which originally predisposed to the disease or accelerated its progress. Sooner or later, in all probability, he again applies to the same or some other hospital, in a still more advanced stage of the malady, from which he ultimately sinks, or has to submit to operation. If the prognosis, therefore, in the affluent classes is favorable, it is far less so among the poor and needy. Where circumstances are favorable, and the treatment commenced at an early period, a few weeks may suffice for recovery with a useful and movable limb; even when portions of the cartilage have been destroyed, the functions of the joint may still be preserved, though the time required becomes considerably prolonged. When the disease

[1] Lectures on the Surgery of Childhood, by Athol Johnstone.

has advanced to suppuration, and sinuses have formed communicating with the joint, recovery can only be expected at the expense of ankylosis, and after the lapse of many months or even some years.

Treatment.—If inflammation is present, we have always to bear in mind that it is of a low character; it is to the relief, therefore, of the constitutional condition that our general treatment has to be mainly directed. Everything which improves the general health—whether in the form of diet, air, cleanliness, or medicine—must evidently increase the power of resisting disease locally, or of remedying its effects. The best means of effecting this improvement, however, have already been so fully described in previous essays, especially in that on SCROFULA (Vol. I.), that it is unnecessary to repeat them here; I need only remark that whatever form of tonic may be selected, it must be given for a great length of time to be of service. As Sir Benjamin Brodie directs, the steel may be administered for three or four weeks at a time, and then suspended for a week or ten days; or some other tonic substituted, if the first should have ceased to agree. Even after recovery has taken place, as the constitution is in fault, it is necessary to persevere with the general hygienic rules prescribed in these cases, if we wish to prevent a recurrence of the disease in the same or some other part.

The *local treatment*, when the disease is seen in its *first* stage, is to a great extent negative. The disease is one of defective power; local depletion, therefore, should be avoided, as a rule, though occasionally a few leeches may be employed to relieve rapidly any outbursts of acute or subacute inflammation. Cold or warm applications can be used at these times, whichever may be most agreeable and soothing to the patient. Counter-irritants, whether in the form of blisters, issues, or the actual cautery, unless in exceptional cases, are seldom required *at this period*, and, indeed, are more likely to do harm than good, by exhausting the patient. They are also objectionable for another reason: these cases usually occur in children, and repeated painful applications, with the frequent dressings subsequently required, induce fits of passion or of apprehension, which are lowering to the patient and injurious to the malady. In fact, in the treatment of children, it is of great moment for the surgeon to acquire their confidence, to inspire them with a feeling of regard and affection; and this can never be done if his visit becomes frequently associated in their mind with pain and suffering. It may of course be necessary at times to have recourse to operative measures, or thorough examinations of inflamed and sensitive parts; but if practicable, these should be done *once for all*, and usually under the influence of chloroform [or ether]. Is nothing, then, to be done locally? *Efficient and prolonged rest*, with the limb in a proper position, here as in scrofulous synovitis, is of the greatest moment, and absolutely necessary to prevent further mischief. The limb should be wrapped in a thick layer of cotton-wool, properly secured, pasteboard or other splints adapted to the form of the joint applied, and the whole secured by gummed or starched bandages, which, without being at all tight, should extend so far as to embrace the joints *above* and *below*, as well as the actual one which is diseased. It is necessary that the limb should be fixed to this extent in order that the contraction of those muscles which arise at some distance from the articulation may be prevented, and the joint kept *absolutely in a state of rest.* Support, to a sufficient extent, should be continued to the part for some time after apparent recovery. It is also desirable that the splints should be so adapted as to allow exercise to be taken, whilst immobility of the joint is maintained.

When the disease has been neglected or improperly treated in its first stage, it commonly happens that the limb has been allowed to become distorted, and more or less fixed in its abnormal direction. In such a case it is better at once to restore the limb to its proper position, of course under chloroform, and to adopt efficient means to prevent it from again becoming distorted. The expediency of this treatment depends not merely on the fact that ankylosis is to be expected (and for recovery by ankylosis to be desirable the limb must be fixed in a proper position), but also on account of its immediate influence on the disease. The painful startings are occasioned by pressure on the inflamed bone-surfaces; and so long as undue and irregular pressure is maintained by the muscles in a state of spasmodic contraction, pain must be experienced and irritation kept up. Dr. Bauer has proposed to divide the tendons of the contracting muscles independent of any malposition, as a means of relieving the starting pains; and such a plan might not unreasonably be adopted if all milder means of relief should prove unavailing. Supposing the disease to be situated in the lower extremity, a long splint is often employed with great advantage as far as mere rest is concerned, but with comparatively little power of relieving articular pressure. For this latter purpose Sir Benjamin Brodie suggested the application of a moderate but constant extending force, by means of a weight attached to a string, passing over a pulley fixed at the bottom of the bedstead, the other end of the string being secured to the limb, whilst counter-extension was kept up by straps, which prevented the body from slipping down in bed. Of late years extension by weight has come pretty freely into use both in America and this country, in consequence of the advantages which it presents, and the facility with which it can be applied. In Mr. Holmes's Surgical Treatment of Children's Diseases, and in some papers by Mr. Marsh, in St. Bartholomew's Hospital Reports, the subject will be found fully discussed; but I may, perhaps, be allowed briefly to illustrate the plan of treatment by means of a case now under my care at the Brighton Hospital for Sick Children.

A girl about six years of age was admitted with neglected hip-joint disease in the second stage. Thigh much flexed and rigid. Knee turned inwards. Pelvis and spine much twisted. No sinuses or other indications of matter, but painful nocturnal startings, and shrieks when the limb is touched. A broad strip of adhesive plaster was applied on either side of the leg from the knee downwards, forming a loop or stirrup some three or four inches below the foot: a flat piece of wood, broader than the foot, was inserted between the two lateral portions of plaster, so as to spread them out and prevent pressure on the malleoli. The plaster was further secured to the limb by two or three circular pieces of strapping, and a light bandage. A stout iron skewer was then passed through a common reel, and the skewer suspended by a couple of straps to the bar at the foot of the child's crib, so that the pulley formed by the reel was opposite the sole of the foot. A bag containing four pounds weight of lead was then fastened to one end of a small chain, the other end being free for the purpose of being fastened to the stirrup of plaster when required.[1] When all was ready, the child was placed under chloroform, and the pillows removed so that she lay flat on her back. On making gentle extension on the thigh, the muscles began to yield quietly, and then one end of the chain, passed over the reel, was hooked on to the stirrup, the four pound weight hanging to the other end some distance from the floor. Straightening of the limb progressed steadily and visibly, and, as this was going on, a long splint was fastened to the opposite or *sound* side of the patient, to correct the lateral twisting of the body and also to prevent any sudden jumping up in bed under the influence of fright. The hip was enveloped in cotton-wool; sand bags were placed on each side of the limb for support; the lower end of the bedstead was raised about three inches by pieces of wood, in lieu of counter-extension, to obviate any chance of the body slipping down; and finally a cradle was placed over the foot to keep off the weight of the bedclothes and prevent eversion. When the effects of the chloroform had passed off, the limb was nearly straight, and the child made no particular complaint of pain, but was cheerful and took her meals. There was some "starting" on the following night, but less than before, and the next day the child was comparatively comfortable and happy.

In the second stage of joint disease, counter-irritation is more often required than in the first. The most generally beneficial form, I think, is the steady and continued use of warm applications over a large surface of skin. Iodine is often of service, and blisters occasionally, though these last had better be employed with care and caution in children. Severe pain, continuing after the limb has been properly secured and sufficient extension made, is often relieved by a few lines of the actual cautery.

In the third stage, when matter is forming, the limb must still be retained in a state of perfect rest and extension. Hot applications, or, perhaps, the actual cautery may be employed, but the pain often continues unrelieved till the matter is evacuated by incisions, or has made its own way through the ligamentous structures towards the surface.

If the case progresses favorably, and the sinuses contract and close, the treatment consists in the same local measures as those which have already been pointed out in the section on *strumous synovitis;* but the case may not progress favorably, and it may then become a question of resorting to *operation.* It has already been stated that in early life the limb may generally be preserved. With the children of the very poor, however, especially those in large towns, and indeed at all periods of life amongst those who have to gain their livelihood by labor, this question often arises: Is the chance, or even the strong probability, of ultimate recovery with a stiffened limb, after many months, perhaps years, of confinement and forced abstinence from labor, preferable to a more immediate recovery with a loss of the limb or joint, but with all the risks attendant on a grave operation? Every case must be decided on its own particular merits; but having this consideration in view, it is evident that a surgeon is often justified in using the knife even where an operation is not absolutely necessary. When health is failing under the protracted confinement, suffering, and exhausting discharge, removal of the part often becomes advisable to *preserve life.* Now in weakly subjects, any thing which lowers the patient, or effects a drain upon the system, is prone to induce disease; the removal of the source of mischief, therefore, often saves life by preventing more important structures from becoming affected. On the other hand, it must be borne in mind that operations in strumous subjects are, in some cases, rapidly followed by the appearance of tubercle in internal organs, which did not previously exist, or, at any rate, had failed to manifest itself. In deciding the point, the surgeon will undoubtedly be influenced by the position and importance of the diseased part, and the consequent severity of the operation required. To expedite the patient's recovery, he would promptly remove one or several of the tarsal bones, when he would hesitate about amputating the thigh, or excising the head of the femur.

---

[1] Fig. 211, Vol. I., p. 947, will illustrate this apparatus.

The comparative merits of amputation and excision have been discussed already. (See the essay on EXCISION.)

The articular extremities of the bones are liable to *rheumatic inflammation*. In the essay on DISEASES OF THE BONES, the subject of *rheumatic osteitis* is described; and its relation to diseases of the joints is further discussed in the sections on Chronic Rheumatic Synovitis and Chronic Osteo-Arthritis, to which the reader is referred.

The joints may also suffer from syphilitic inflammation commencing in or extending to the bones. For this also the reader is referred to the essay on DISEASES OF THE BONES; and some further remarks on the subject will be found under the head of syphilitic synovitis.

Rachitic affections of the articular ends of the bones.—The bones are materially affected in the constitutional derangement giving rise to rickets. This condition, which is sometimes supposed to be of modern origin, though the lines of Martial[1] would seem to show that it could not have been unknown in his time, is described in another part of this work.[2] It is only necessary to remind the reader here, that though the alterations which occur are specially manifested in the *shafts* of the bones, yet the articulations do not entirely escape. In the early stage of rickets the "knots" or swellings which take place in the osseous or cartilaginous ends of the bones are highly characteristic of the affection. At the anterior extremities of the ribs these enlargements are particularly obvious, affecting both the bone and the cartilage, and giving rise to an angular projection of the costochondral articulations. At a later period these articulations become much weakened, and permanent alteration of shape occurs. Sometimes the rib projects, and the cartilage is forced inwards; more frequently it is the rib which is driven inwards, and the cartilage is dislocated on its external surface, a connection between the two being still maintained by ligamentous tissue. If the chest is examined, the extremities of the ribs will be found presenting a row of nodosities, the sides of the thorax are hollowed, the thoracic capacity diminished, and the function of respiration interfered with to a more or less serious extent. In the limbs, similar nodosities are met with in the articular extremities of the bones, first appearing in the lower ends of the radius and ulna, as well as in the malleoli, and afterwards affecting the knees and elbows. As the disease advances, the shafts of the bones undergo the alterations described elsewhere, the bending of the diaphyses occurring more frequently, as well as at an earlier period, in the lower than in the upper extremities. The articulations participate more or less in the deformity, being often twisted in an opposite direction to the curvature which the limb has assumed. The ligaments yield, and incomplete dislocations are apt to take place. At the knee, for instance, displacement may occur outwards or inwards, resulting from a partial yielding of the articular extremities of the femur and tibia, itself induced by the unequal distribution of the weight of the body on the surfaces at the joint.[1]

The nature of the affection, when the joints are implicated, can scarcely fail to be recognized, in consequence of the rickety condition of other parts of the osseous system, and the period of life at which it occurs. The treatment in these cases is mainly constitutional, to remedy, if possible, the specific diathesis: cod-liver oil, probably, being the medicine which is most generally beneficial. Locally, it is advisable in most instances, when the articulations are disposed to yield and to become distorted, to apply mechanical support of such a nature as to counteract the tendency to displacement, and allow of exercise being freely taken. The articular deformity in this way is often relieved, and the results obtained are tolerably satisfactory.

Tumors of the articular ends of the bones.—In the essay on DISEASES OF THE BONES an account of the new formations which occur in connection with the osseous system has been given. If the articular ends are involved, the joints may evidently become affected either by their movements being mechanically interfered with, or, in the case of cancer, by extension of the disease to other structures, and consequent disorganization of the articulation. The symptoms, therefore, produced by these formations, especially the malignant, present certain points of resemblance with those of other diseases of the joints, which may be briefly noticed. In some cases, the nature of the tumor for various reasons is obvious enough, and no difficulty arises in the diagnosis, but this is far from being generally, or even usually the case; the rules, however, by which we are to be guided are laid down in the essay to which the reader has already been referred. The form of malignant disease most frequently met with is the soft or medullary, and according to Rokitansky it never commences, as a primary disease, within or upon the synovial membrane; the same remark applies with increased force to the cartilages, for the cartilaginous structures are sometimes found intact when every other part of the joint has been destroyed.[1] Whatever may be effected in the case of innocent formations, in malignant affections the only chance of relief consists in amputation, which should be performed, if possible, so as to remove the whole of the affected bone. Even when this is done, the chance of permanent success is far from great; but amputation involving the retention of any portion of the cancerous bone is next to hopeless. Obviously, therefore, it is desirable to ascertain in which of the bones the disease began; and by attending to the point where the swelling first manifested itself, this can usually be determined.

Abnormal Conditions of the Articular Cartilages.

The articular extremities of the bones are protected by a thin layer of cartilage, one surface of which is firmly connected with the bone, whilst the other is free in the joint, except near the circumference, where it is covered by an extension of the periosteum, forming a special coat—*perichondrium*—which gradually terminates on the cartilage, without any well-defined border. It is to this perichondrium that the portion of synovial membrane which advances over the edge of the cartilage is inseparably united.

The articular cartilages, when fully developed, contain neither nerves nor bloodvessels, and yet they are living tissues, though simple in their structure. Nutrition in them, as in the cornea, is not effected directly through the means of bloodvessels, but results from the conveyance of the nutrient materials from cell to cell. The cartilage-cells retain their powers of reproduction; old cells disappear and are replaced by new ones, and so a round of nutritive changes takes place adapted to serve the wants and maintain the integrity of the tissue. The nutrient materials are obtained from the bloodvessels of the synovial membrane and of the bone; in both cases there exists a free vascular supply in close proximity to the cartilage, round the circumference of which are arranged the *plicæ vasculosæ* of the synovial membranes; whilst we find in the bones, beneath the cartilaginous surface (the *articular lamella*, however, intervening), vascular convolutions, dilatations, or plexuses, specially adapted for the reception of the blood and separation of its plasma.

The functions of articular cartilage are comparatively mechanical, intended as it is by its smoothness and elasticity to diminish friction and obviate the "jar" or shock to the bones, which would otherwise give rise to frequent fractures. Even for these purposes, however, it is necessary that a certain amount of vitality or nutritive power should exist, else the cartilage would gradually wear away in proportion to the amount of friction it has to sustain, and that we know is not the case; for if articular cartilages are somewhat thinner in the old than in the young, the change is not greater than that which is known to occur in other tissues of unquestionable vitality.

So long as the natural processes of nutrition and secretion, as well as the disturbed processes of inflammation, were attributed entirely to some mysterious action on the part of the bloodvessels, the healthy and diseased conditions of the non-vascular tissues scarcely allowed of explanation. But when we admit the nutritive power of the cell- or germ-constituents of the tissue itself, and consider the vessels as intended to bring supplies of prepared nutriment into sufficiently near relation to them, much of the difficulty vanishes. In perfectly developed articular cartilage we have permanent nucleated cells contained in their capsules and imbedded in an inter-cellular substance; and if we have no vessels in the cartilage itself, they exist in sufficiently close proximity to the tissue for the elements they contain to be within reach of the more direct agents of nutrition. Such an arrangement would be insufficient for organs in which intense action is going on; but for the passive cartilages, the bloodvessels of the bones on which they rest, and of the synovial membranes which surround their circumference, afford a sufficient supply of nutritive material for the cartilage-corpuscles to maintain the integrity of the tissue. If this supply is interfered with, if the circulation in the bone or in the synovial membrane is disturbed beyond a certain point, we can understand that the nutrition of the cartilage should be prone to suffer, and so we find this tissue very liable to be affected *secondarily* in consequence of inflammation, common or specific, occurring in the synovial membrane or in the articular extremity of the bone. Its nutrition, however, may also become abnormal, directly or primarily, from some disturbed action in its own elements, and we have disease of the cartilage, attended with great alteration of structure, where the neighboring tissues exhibit little or no sign of disease.

---

[1] See Virchow, Cell. Path., Lect. xix.

Articular cartilage then is so far under the influence of the laws which regulate vital tissue as to be at once capable of maintaining its own status during health, and of undergoing changes, many of which are analogous to those termed inflammatory, in a state of disease. Thus cartilage will maintain itself in its usual condition during a long life; it may be hypertrophied or atrophied; it may degenerate, may ossify, or perish; it may also ulcerate, and probably suppurate.[1]

Hypertrophy.—Articular cartilages, it is said, are occasionally found to present an increase in their substance without any obvious change in their actual texture. Such a condition, however, appears to be very rare; for, as a general rule, when the cartilage is thicker than natural the tissue is soft and spongy, with a tendency to break up into fibres, exhibiting, in fact, obvious marks of disease.

Atrophy.—Simple wasting of the tissue in cartilage occurs more certainly than simple hypertrophy. In advanced life, and especially in those joints which are subjected to the greatest amount of pressure, such as the hip, we find the cartilages gradually thinned, their structure in other respects remaining healthy. The process is, of course, a slow one, advancing gradually with age, and constituting, in fact, little more than a sign of natural decay. True atrophy, in most cases, affects the whole surface of the cartilage; but a partial thinning is met with in comparatively early life, accompanied usually with sufficiently marked traces of previous disease to distinguish it from simple wasting.

Gouty deposits in cartilage.—In old and gouty subjects we sometimes meet with a peculiar change in the articular cartilages, resulting from the deposit in their substance of urate of soda. This salt is found not merely on the surface of the cartilage, but also in the inter-cellular substance, through which it is diffused, sometimes to such an extent as almost to supersede the normal structure, which then presents the appearance of a chalky mass. The predilection exhibited by the gouty material for this tissue is further shown by the frequency with which it is deposited in the cartilage of the external ear as well as in the articular cartilages.

Fatty degeneration of cartilage.—In advanced life, in joints which have long been disused, and under other circumstances unfavorable to healthy nutrition, articular cartilages sometimes undergo a process of degeneration corresponding to the analogous affection of the cornea, which passes by the name of *arcus senilis.* In such cases we find the whole or part of the articular surface presenting a series of fibres, free at one extremity where they project into the articulation, and attached at the other to the remaining cartilaginous tissue, exhibiting, indeed, somewhat the appearance of velvet. The cartilage is often thickened and pulpy, and much softer than natural, or it may appear rough and fibrous.

Ossification of cartilage.—Many cartilaginous structures have a natural tendency to ossify as age advances, and we find the costal cartilages usually, and the thyroid and cricoid cartilages occasionally, undergoing this change, which represents in them a form of degeneration or decay. The articular cartilages, on the other hand, are by no means prone to such a transformation; for, when the developmental ossification is completed, any further tendency in this direction appears, as a rule, to be permanently arrested in the cartilage which remains beyond the articular lamella. Under certain circumstances, however, articular cartilage becomes converted into bone. This change, occasionally met with in the aged, is obvious enough at times during the progress of *chronic osteo-arthritis;* for in joints suffering from the affection, the place of the entire cartilage may be occupied by a particularly dense kind of bone, in which the Haversian canals are filled with calcareous matter; or portions of the cartilage may be replaced by this ivory or porcellanous material, which remains on a level with the remaining cartilaginous structure.[1]

Ulceration of cartilage.—It has been already stated, in accordance with the opinion of Weber,[1] that articular cartilage, like the cornea, is very liable to an altered condition of nutrition, which may fairly be called inflammatory; a condition which shows itself principally in the form of ulceration. The researches of Goodsir and Redfern, followed by those of still more recent authors, have shown that the changes in ulceration arise immediately from a vital alteration occurring in the cartilaginous structure itself, and that the influence of the neighboring bloodvessels is only indirect or secondary. When the disease is peculiarly active, almost the whole of the cartilage may disappear, a few isolated patches, which are usually reddened, alone remaining. In other cases, the cartilage is softened and abraded; or it appears as if portions of it had been scooped out, leaving smooth pits or depressions. Ulceration usually begins on the free surface of the cartilage; it may commence, however, on its attached surface, or even in its substance.

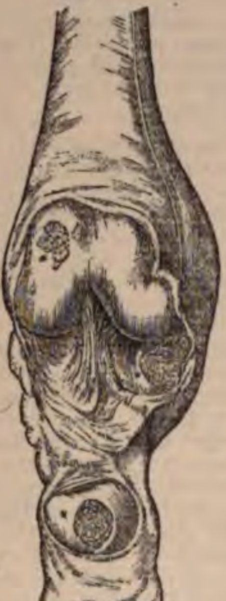
Fig. 667.



Incipient ulceration of cartilage. (Museum of St. George's Hospital.)

If we examine the change as they occur on the free surface after synovitis, we notice that the color of the cartilage is altered in spots, which either rapidly become holes, looking, to use Sir Benjamin Brodie's expression, "as if they had been cut out with a chisel," or the spots assume a fibrous aspect, becoming gradually excavated, so as to form pits or depressions with fringed margins. Such a condition may be found destroying the cartilage extensively, and even laying bare the bone, without the presence of any membrane. In many cases, however, and especially in scrofulous synovitis, we find a thickened or newly-formed vascular membrane extending from the diseased synovial capsule over the cartilage. Such an extension, indeed, may occur without any ulceration resulting; or even when the cartilage is affected, the excavations are not at first necessarily in connection with the membrane, for they may be found in situations to which the membrane has not extended. As the disease goes on, however, the cartilage, according to Mr. Barwell[1] (in his description of the changes occurring after strumous synovitis), slowly undergoes a transformation into a form of granulation, between which and the similar material growing from the synovial membrane adhesions form, resulting at last in absolute continuity. If the ulceration extends deeply, the bone beneath participates in the disorder, its vascularity is increased, and at last the cancellous tissue becomes inflamed. The articular lamella crumbles, or gives way in masses, carrying with it portions of cartilage, which may still be comparatively sound; and the granulations which spring from the exposed cancellous tissue unite with those of the synovial membrane. When the disease originates in the bones, and extends to the cartilage, the first process, according to Mr. Barwell, is one of simple degeneration, followed usually by true inflammatory ulceration. A portion of the cartilage, losing its nutrient supply, degenerates or perishes, and is detached with its articular lamella from the inflamed surface of the bone, whilst the surrounding portions of cartilage undergo

[1] Barwell, On Diseases of the Joints, p. 113.

the changes described as occurring in ulceration after synovitis. Inflammatory ulceration of the cartilages, unaccompanied with disease of any other joint-tissue, may *possibly* take place, though cases of it are not easily met with; degeneration, on the other hand, being of comparatively frequent occurrence.

[Primary ulceration of the cartilage unconnected with disease of the bone or synovial membrane has, according to Hueter, never been demonstrated.

Sir Benjamin Brodie claimed to have shown primary ulceration of the cartilage, but failed to make a sufficiently thorough examination of the bone to exclude osteal origin of the disease.[1] Panas[2] claims to have frequently seen erosion or ulceration of the cartilage unconnected with a lesion of the bone or synovial membrane, in cadavers perfectly normal in other respects, but he thinks there is no reason to believe that tumor albus originates in either disease of the cartilage or ligaments.[3]]

When the cartilages have been extensively destroyed and the cancellous bone-tissue on each side of the joint exposed, repair, if it occurs, takes place by granulation-tissue uniting the opposing surfaces, and producing ankylosis in the manner already described. Or the ankylosis may be incomplete, portions of cartilage still remaining unaltered. In slighter cases, a natural cure may occur after ulceration has gone on for some time, and affected the cartilage to a considerable depth. This takes place, as Dr. Redfern points out, "by the formation of a fibro-nucleated membrane from the substance of the cartilage, without the occurrence of any new exudation." Occasionally we find a patch of ivory deposit occupying the place of some portion of the cartilage, or there may be simply a scar left, marking the place where the ulcer had existed. To complete the sketch of the changes which this tissue undergoes, it may be stated that, in cartilage, malignant affections are so rare that it is usually assumed to be altogether insusceptible of them.[4] For this insusceptibility Virchow gives reasons, founded on his views of the transference of the infection, by means of morbid juices, to the anastomosing elements in the neighborhood.

Symptoms.—Lesions of cartilage may occur primarily or secondarily. As primary affections, we frequently find after death well-marked "ulceration" where no symptoms had been noticed during life, excepting, perhaps, occasionally, a certain amount of "crackling" or "grating" in the joints. These cases are of course chronic in their character, and the affection is of the nature which has been described under the head of degeneration. True "inflammatory" ulceration is almost invariably secondary, the consequence of inflammation, common or specific, occurring originally in the synovial membrane or in the bone. This affection may be acute or chronic in its progress. Sir W. Lawrence[1] relates the case of a patient who died after venesection, in whom, as he believed, complete destruction of the articular cartilages of the femur and tibia took place in four days. In most cases, however, it is much slower in its progress; and in some, especially in old disease of rheumatic origin, it may be extremely chronic in its character.

Degenerative ulceration of cartilage is attended with no marked symptom, gives rise to no pain. Is pain produced by "inflammatory" ulceration? The deservedly great authority of Sir Benjamin Brodie for a long time connected with ulceration of the cartilages those severe pains which are increased at night-time, aggravated by any motion, and attended with involuntary startings of the limb. The fact, however, that no nerves can be discovered in articular cartilage, even with our present improved powers of investigation, renders such a view almost inadmissible, unless we conclude that our means of investigation are still too defective to warrant our placing trust in them. In his last edition, however, Sir Benjamin Brodie avows that he is "inclined to the opinion that the increased sensibility in these cases is in the bony plate beneath the cartilage, rather than in the cartilage itself; and that the presence of severe pains with involuntary startings of the limb, is always to be regarded as a sign of the bone partaking of the disease." We may assume then, that disease of articular cartilages is attended with no distinctive or characteristic symptoms (if we except the "crackling" on motion, mechanically attendant upon a loss of smoothness of their surface). In cases of disease commencing in the synovial membrane, when starting pains come on, it may be taken indeed as evidence, not merely that the cartilages are affected, but that the disease has further extended to the bone. When the disease, on the other hand, has com-

menced in the bone and involved the cartilages, the joint may speedily become opened; and the suppuration and abscess which occur there are attended with the symptoms which have already been pointed out. The treatment, as well as the diagnosis of diseases of articular cartilage, so far as they can be ascertained, will be found in the description of the affections of the other structures of the joints.

[AFFECTIONS OF THE JOINTS SECONDARY TO CHANGES IN THE SPINAL CORD.

Articular affections dependent upon and secondary to lesions in the spinal cord have been demonstrated by Charcot, Ball, Allbutt, Raymond, Hitzig, and others. The pathological changes are directly dependent upon the changes in the cord, and are said to have been observed after injuries of the peripheral nerves, cerebral apoplexy, acute myelitis, tumors in the gray substance of the cord, and in Pott's disease. The most common spinal arthropathy is that following degeneration of the posterior columns, or locomotor ataxy, and is characterized by a hydrarthrosis, together with a diffused swelling of a hard consistency, involving the tissues about the joint, and without the ordinary symptoms of œdema. The joint is distended with fluid, but the swelling is not limited to the cavity of the joint, and hence the characteristic appearance observed in hydrops articuli is wanting. The course of the affection is varied. The swelling may disappear suddenly after a few weeks' or months' duration, without any injury to the joint, or erosion and absorption of the articular ends of the bone may follow, with luxation of the bones and total destruction of the joint. Suppuration has been observed, but is exceptional. The disease is always an early phenomenon, occurring between the prodromal period and that of inco-ordination.

The knee is the joint most frequently affected, then follow in order the shoulder, the elbow, hip, wrist, and smaller joints. Several joints may be affected at the same time.

"Certain arthropathies," to quote the opinion of Vallin, "are only the local expression of a trouble of nutrition, with its origin in a lesion of the cord; they are frequently confounded with traumatic joint affections, but a difference exists which permits a diagnosis."[1]]

DISEASES OF OTHER TISSUES IN AND AROUND THE JOINTS.

We have seen that the diseases of the joints, which I have attempted to describe, are prone to affect in their progress the soft structures in the neighborhood. The ligaments become relaxed and weakened; the muscles contracted; the areolar tissue forms the seat of abscess, or is traversed by sinuses; and the skin itself may be ulcerated or destroyed. The morbid action, on the other hand, may *originate* in the peri-articular structures, and either simulate disease of the joint or lead directly to it. The variety of these lesions is so great that it is impossible, within the limits of this essay, to attempt a detailed examination of them, and this indeed would be unnecessary, as their description will be found in other parts of the work. A few remarks, however, upon the relation of each of these structures to the pathology or diagnosis of joint-disease may not, perhaps, be considered out of place.

Diseases affecting the Ligamentous Structures.

The ligaments and fibrous structures around the joints are no doubt liable to inflammation, acute or chronic, in consequence of the injuries which they sustain from sprains or other accidents (see the essays on injuries of the different regions). Slow to inflame, the reparative process appears to be slow also; for it frequently happens that the movements of a joint are hampered, and its use attended with great pain for a long time, after a comparatively slight injury, in which the ligamentous or tendinous tissues alone have apparently been injured. Opportunities of examining the parts in these chronic cases have not often been afforded, or have not, at least, been often made use of; but occasionally the ligaments have been found thickened and pulpy, independent of any actual laceration of their substance. From the frequency with which chronic or "strumous" joint-disease can be traced to some slight accident or injury, it is very probable that, in some cases at all events, the ligamentous structures are the textures originally affected, and Mr. William Adams is even

of opinion "that strumous disease commences most frequently in some of the ligaments of the joints." At any rate, in the case of the hip, the ligamentum teres and other parts of the ligamentous apparatus are found so often affected, and at so early a period, that there is much reason to believe that the disease may in many instances originate in these structures.

[Against this view may be cited autopsies where the ligamentum teres in cases of early hip-disease was not found destroyed. Further, according to Hyrtl,[1] the artery in the ligamentum teres does not supply the nutrition of the head of the femur. It does not enter the bone, but on reaching it returns back in the ligamentum teres. This opinion of Hyrtl, however, is not held by many anatomists.]

In the sketch of the advanced stages of articular disease we have seen the ligaments ulcerating or yielding, and so permitting the exit of matter from the interior of the synovial membrane, or allowing complete or partial luxations to occur. Sometimes, on the contrary, we find layers of a fibrous tissue, having somewhat of a lardaceous appearance, and occasionally attaining a very considerable thickness, developed in the ligaments or in the areolar tissue around them, and forming the immediate cause of what is termed extra-capsular false ankylosis. In rheumatic and syphilitic affections, it is probable that the ligamentous structures share in, or even originate, the diseased action, and at least contribute to the pain which is so severely felt. In gout they may form the seat in which the urate of soda is deposited. In chronic rheumatic arthritis they suffer to a great extent; the capsular ligaments may be greatly increased in thickness, or portions of bone may be developed in their substance; and in the hip the round ligament may entirely disappear, or in the shoulder no trace of the glenoid ligament be left.

The ligaments, it was said, are liable to become relaxed in the progress of articular disease; a similar looseness of them is sometimes found as a primary affection, or at least dependent only upon some constitutional condition. In persons of lax fibres, especially in delicate or hysterical young women, a preternatural mobility of the joints is not uncommon, so that extension of the fingers or thumb may be carried nearly as far as flexion, and the nails and the back of the hands be made to meet. In many cases this state is not attended with any practical inconvenience; and even where partial luxations occur, the bones return at once to their normal position. Occasionally, however, it happens, perhaps in those persons in whom the undue mobility of the joints is not attended with a corresponding relaxed condition of the muscles, that complete dislocation takes place, which may not be reduced spontaneously, but may require surgical assistance. Instances of this kind, involving an unusual liability to luxation, are frequently recorded. A similar condition of relaxation of the ligaments, involving loss of power of the articulation, and leading occasionally to luxation, may follow palsy of a limb, and is often met with as a result of infantile paralysis. In many children it is necessary to have recourse to mechanical contrivances to obviate this weakness, whilst means are being adopted to increase the muscular power by which the joint may be moved or the limb exercised. The symptoms, progress, and treatment of articular disease, as it implicates the ligaments, will be found included in the preceding sections.

[The reflex symptoms accompanying joint affections have been recently the subject of a good deal of attention.

M. Ollivier has well stated the present opinion in regard to the changes which occur:—

"Le systéme musculaire éprouve le contrecoup de presque toutes les affections qui peuvent atteindre les jointures."[1] This "contrecoup" is manifested in the early stages by what is well termed "éréthisme de la contractilité musculaire"—or to use another figure, "vigilance musculaire." This state of muscular irritability is manifested by a liability to a spasmodic contraction of the muscles, or by a resistance to passive motion, "a reluctance of the muscles to relax." This irritability may be replaced by a permanent contraction, which if persisting a long time will develop a fibrous degeneration of the muscle.

Atrophy also takes place quite rapidly, more so than can be explained on the supposition that it is caused by the rest the limb is subjected to. This atrophy is an early symptom, and may be supposed to be due to a reflex change in the trophic cells of the cord, supplying the limb, or to a change in the nerves about the joint.[2] In addition to this a diminution in the faradic muscular contractility in the muscles about the joint has been demonstrated by many.[3]

[[1] Boston Med. and Surg. Journal, May 10, 1877, p. 568.]

[[1] Thèse de Paris, 1859.]

[[2] Valtat, de l'Atrophie Musculaire dans les Maladies Articulaires, Paris, 1877.]

[[3] Webber, Putnam, Trans. Mass. Med. Society, 1878; Seguin, Shaffer, Archives of Clinical Surgery, June, 1877.]

The reflex symptoms; muscular stiffness, muscular contraction, atrophy and diminution of the elastic contractility of the muscles, are so marked that they have been considered as diagnostic of joint affections.

Some writers regard a firm contraction of the muscles, atrophy, and loss of electric contractility, as indicative of an affection of the joint characterized by an osteitis in distinction to a synovitis.[1] But the subject needs further investigation, as all observers do not agree as to the reliability of all these symptoms as a means of diagnosis between synovitis and epiphyseal osteitis.[2] The writer met with one case of osteitis, where from the rapid atrophy and muscular rigidity about the hip-joint, a chronic articular osteitis was diagnosticated; but on autopsy six months later, it was found that no disease of the bone was present, but a marked synovitis.[3]]

Diseases affecting the muscles.

The altered conditions of the muscles and their tendons by which the joints are forced into certain positions, or retained in the positions they have assumed, may be primary or secondary in their relation to the articulation. In the latter case disease commences in the joint, and the muscles are affected subsequently, contracting spasmodically from reflex irritation, so as to aggravate the symptoms and give rise to increased mischief by the inter-articular pressure they produce, as well as by the tendency to partial or complete luxation caused by the predominance of one group of muscles over its antagonists; at a later stage, too, they become fixed and rigid, so as to impede functional exercise of the joint even when the original articular affection is subdued. Hence the importance, which has already been insisted on, of early attention to the position of the limb, and the necessity of counteracting the reflex muscular action by appropriate splints or by properly applied extension. The muscular lesion, on the other hand, may be primary, as far at least as the joint is concerned; from some disturbance in the nervous system, an undue or unbalanced contraction of certain muscles occurs, and the articulation is fixed in a particular position, which becomes permanent if the muscular structure degenerates and loses its proper contractile material. Such a condition of spastic rigidity is sometimes found in the adult, the result usually of serious disease affecting the cerebro-spinal axis. It is much more common in early life, as a consequence of the infantile paralysis which, if seldom fatal, is frequently quite incurable. In many of these cases the amount of deformity which occurs is deplorable, and the malposition of the joint, so long as it lasts, obviates any hope of stimulating the muscles to contract, or prevents that exercise of the limb on which any prospect of improvement depends.

Rigidity of the muscles, terminating, perhaps, in atrophy or degeneration, is often seen when a limb has been maintained for too long a time in one position, and especially when pressure has also been exercised on the muscles and their tendons, and their action arrested by the application of tight bandages. This condition of the muscles may also be accompanied by grave mischief within the joint. After fractures requiring prolonged immobility of the limb, or at least in which the limb has been kept fixed for a length of time, rigidity of the parts takes place to a greater or less extent, and is very obstinate in its duration. In some of these cases, and especially when the patient is advanced in life, or the constitution is otherwise predisposed to such alterations, we may find, as M. Tessier has pointed out, effusion of serum, mixed perhaps with blood, into the joint, the synovial membrane at the same time being injected and its vascular fringes swollen. In other cases the mischief may have advanced still farther, and the articular cartilages have materially suffered, becoming reddened from contact with the effused blood, and softened in their structure, or presenting actual loss of substance on their surface. These changes, it may be remarked, are not confined to the articulation in the immediate neighborhood of the fracture, but extend to others which have been maintained in a similar state of fixedness. The importance of due action of the muscles need scarcely, therefore, be insisted on, or the propriety of having recourse to passive motion at the earliest period of which the case will admit.

Finally, it may be noticed that an articulation is sometimes found to be perfectly rigid, from muscular contraction, in that condition of the nervous system which we term hysterical (see Articular Neuralgia). By examining the limb, however, during natural sleep, or in the insensibility produced by chloroform, the relaxed condition into which the muscles fall, and the free movements which can

be impressed upon the joint, leave no doubt as to the true nature of the case.

The subject of undue or impaired muscular contraction, and its results, will be hereafter treated in the essay on ORTHOPÆDIC SURGERY; but it plays so important a part in articular disease, that it was impossible to avoid all notice of it in this place.

Diseases affecting the Areolar and Adipose Tissues.

The areolar tissue around the articular extremities of the bones, or over the synovial membranes, commonly participates in the diseases of these structures, and is either simply œdematous, or, in severe cases, becomes the seat of abscess or permeated by sinuses. Acute inflammation, on the other hand, not unfrequently attacks the areolar tissue in the neighborhood of joints, as the result of blows or contusions, of wounds, or of erysipelas. It occurs, too, in many cases as a secondary consequence of inflammation of the synovial bursæ. The inflammatory action frequently runs high, and there is much constitutional as well as local disturbance. The swelling is considerable, the part is hot and tender, the skin reddened, and any movement of the part, including the articulation, is attended with pain. There is usually much tendency to suppurate, and when the synovial bursæ are implicated, matter forms rapidly and in considerable quantity, presenting some resemblance to acute abscess of the articular cavity. The diagnosis, however, between this affection and disease originating within the joint, is not difficult. The rapidity with which the symptoms have come on distinguish it from disease of the bones; whilst the position of the swelling, which extends over and conceals the osseous prominences, prevents it from being confounded with synovitis. By careful manipulation, too, it will be found that the joint itself may be handled without producing pain, provided that no pressure or tension is exercised upon the inflamed parts around. This kind of inflammation is not uncommon in delicate or strumous children, in whom it is very apt to involve the articulation, unless great care is taken. The knee and the shoulder are the two situations, perhaps, in which the affection is most frequently seen.

The treatment in these cases is sufficiently obvious. The limb must be kept at perfect rest; poultices and fomentations applied; and if matter forms, early and free incisions should be made for the purpose of evacuating it, lest the pus should find its way into the synovial cavity, and the case become one of serious consequence, resolving itself, in fact, into acute suppuration of a joint. The incisions, though free, should not, of course, be so deep as to open the articulation, under the mistaken idea that this is already implicated. In strumous children the general health has to be sedulously attended to, and care taken not to depress the constitutional powers.

With respect to the affections of the adipose tissue, there is little to be said; according to Rokitansky, a branching growth of fatty tissue is occasionally met with, chiefly in the knee-joint, in the free part or in the duplicatures of the synovial membrane, corresponding to the lipoma arborescens of J. Müller.

Diseases of the Synovial Bursæ.

A description of the pathological affections to which the synovial bursæ are liable will be found in the essay on AFFECTIONS OF THE MUSCULAR SYSTEM, to which the reader is referred. The situation of the subcutaneous bursæ, at least of those which are most liable to disease, is well known, and they are at once so accessible to examination, and the symptoms attendant on their morbid conditions so characteristic, that mistakes concerning them are hardly likely to arise. In the case of the deep-seated bursæ, however, this is by no means so certain. Their diseases simulate to a much greater extent disease of the neighboring joints, and, indeed, frequently lead directly to it; for in many instances these bursæ are continuous, or have some connection with the articular synovial membranes, so that direct extension of inflammation may occur from one to the other. In the description, therefore, of the special characters which attach to the diseases of the individual joints, I shall have occasion again to refer to the deep-seated bursæ, and to the means of distinguishing their affections from those of the articulations.

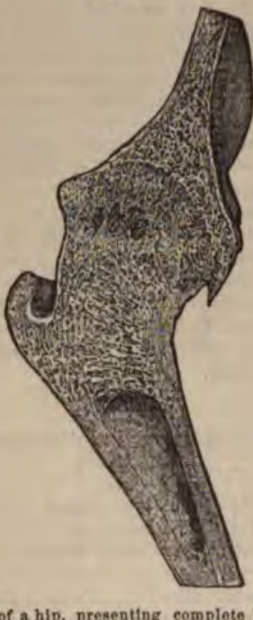
Altered conditions of the Integuments around the Joints.

The diarthrodial joints are intended to allow of free movements of the bones which enter into their composition. If these movements are interfered with, the joint is truly affected, whether the seat of the obstruction is in one of the proper articular structures, or has only an indirect connection with them. Whenever the integuments have been extensively destroyed around a joint, the resulting cicatrix, and the accompanying induration of the subcutaneous areolar tissue, may cause the articulation to be partially or almost wholly rigid. The cases in which this usually occurs are those resulting from extensive burns; and here too we often find a limb rendered useless, and hideous deformity produced, by the original extent of the injury, or by the want of proper forethought during the healing process. In the essays on BURNS and on PLASTIC SURGERY, the importance of considering the position to be chosen for the limb, when the burn has invaded the circumference of an articulation, has been pointed out, as well as the best means to be adopted for preventing injurious contraction at the time, or for remedying it if it has unfortunately occurred. I have thought it right, however, not entirely to omit in this essay any allusion to the fact that a natural condition of the surrounding integuments is of importance to the integrity of the joint.

ANKYLOSIS.

A want of precision occasionally attaches to the sense in which the term ankylosis is used. Originally, as the word itself implies, it was applied solely to joints which had become fixed in an *angular* or bent position; rigidity when the limb was straight receiving another designation (ὀρθόκωλον). The position which the limb has assumed is no longer specially designated, but we speak at the present day, somewhat clumsily it is true, of ankylosis as being *true* or *false*; the latter, at any rate, having a somewhat vague signification in the minds of many authors. By *true ankylosis* (*synostosis*) is meant actual osseous union of the contiguous bones. This implies, in most cases, destruction of the entire joint, and constitutes a further or final stage of the process of junction by fibrous tissue, which has been described in previous sections, and which forms one variety of false ankylosis. A form of osseous ankylosis, moreover, is sometimes met with in which the new bone is placed *outside* the articulation. This variety is most common in the spine, which occasionally presents superficial bridge-like bony processes extending from one vertebra to another, or even forming a kind of osseous sheath enclosing several vertebræ.

Fig. 669.



Section of a hip, presenting complete bony ankylosis of the ilium and femur. (From a preparation in the Museum of St. George's Hospital.)

False ankylosis may be *intra-capsular*, when it signifies a junction of the articular surfaces of the contiguous bones by a comparatively soft or membranous tissue (the joint-cavity being partially or completely destroyed), or it may be *extra-capsular*, the union of the bones in this case depending on adhesions around the articulation, with thickening and induration of the capsular or ligamentous tissues in that situation. The latter, or extra-capsular false ankylosis, usually accompanies the former; but it may exist alone, as was seen in a case related by M. Bonnet, where the articulation was completely fixed even when section of all the muscles around had been performed after death, whilst the interior of the joint was found to be perfectly healthy, the ankylosis resulting from the presence of an enormous mass of fibrous tissue in the ham, uniting the femur to the tibia.[1] Impaired mobility of the joints may result, no doubt, from other causes. In chronic osteo-arthritis, for instance, the shape of the articular surfaces is altered, or bony vegetations are formed around them, which mechanically impede or arrest motion. The joint may be crippled by the contraction of cicatrices after injuries or diseases affecting the integuments and contiguous tissues. Muscular retraction, too (so often present in and complicating ankylosis), may alone interfere with freedom of movement. These cases, however, may be termed "articular rigidity," rather than ankylosis.

Ankylosis is occasionally seen in advanced life affecting some of the minor joints without the existence of much obvious cause to account for its presence. As a rule, however, ankylosis, whether true or false, results from inflammation, common or specific, which has affected a joint, and produced a certain amount of destruction of the parts, followed subsequently by reparative action. In the majority of joints there is little difficulty in determining the fact that motion is at least impaired, if not altogether lost. In the hip and shoulder, however, it is necessary to be careful that increased mobility of the pelvis (especially noticed in children) or of the scapula is not mistaken for action of the articulation. The determination of the exact cause of the rigidity is not always easy. In chronic osteo-arthritis, irregular osseous processes may, perhaps, be felt, and the character of the deformity will assist in the diagnosis. When retraction of the muscles is the sole or principal cause of the impaired mobility, the tendons may be felt rigid beneath the skin. If the areolar tissue around the entire joint or at one part of it is indurated, inextensible, and traversed by sinuses, we may suspect that the extra-capsular form of false ankylosis is not entirely absent. If some degree of motion, however slight, can be given to the joint, we *know* that true or osseous ankylosis is not present; although the converse of this is not equally certain, for in false ankylosis the firmness of union may be so great as to render it difficult to detect any motion, even when muscular opposition is removed by means of chloroform [or ether].

---

[1] Bonnet, Sur les Maladies des Articulations, tome i., p. 130.

Treatment.—It has been already explained that a time may come in the progress of articular disease when it is necessary to exercise the joint; when passive motion must be had recourse to, and friction in its various forms assiduously employed. These measures constitute what may be termed the preventive treatment of ankylosis. Supposing that they have not been adopted, or have been inadmissible, and ankylosis has actually taken place, the treatment will depend greatly on the position in which the limb has become, or is becoming, rigid. If the position is suitable, in true ankylosis (synostosis), so slight an amount of further improvement can be hoped for, that no interference will probably be attempted. In false or fibrous ankylosis, on the other hand, if the case is seen at a sufficiently early period, the general plan of what was termed preventive treatment may usually be employed with safety to prevent soft union from becoming osseous, and also to increase such mobility as may be present, by stretching the soft uniting structures, and so adding to the usefulness of the limb.

Unfortunately it too often happens, from ignorance or carelessness on the part of the patient or his friends, possibly even in a very few cases, from remissness on the part of the surgeon in not sufficiently guarding against malposition in joint-disease, or from his hesitating to correct it at its commencement, when simply dependent on muscular spasm, that the joint may have become ankylosed in the original sense of the word, or at least in a *faulty* position, for the same position is not of equal use in all articulations, or even in all classes of persons; in certain trades, for instance, a special position is often desirable. Early treatment, then, is necessary, if the limb is to be rendered serviceable, instead of becoming simply an incumbrance. Supposing the case to be one of false ankylosis, the first thing to be done is, to place the limb in that position in which it may be employed to the greatest advantage, and subsequently, when inflammation has subsided, to increase the mobility of the joint, if any increase is considered possible. The means at our disposal for the purpose of relieving the deformity have been augmented by modern discoveries: by the employment of chloroform we annihilate pain, and get rid of the active muscular contraction which would greatly impede our efforts; and by means of subcutaneous surgery we are furnished with a safe and ready method of overcoming the passive or permanently rigid state into which some of the muscles are likely to have fallen; a state which adds materially to the resistance offered by the joint.

The replacement may be immediate or gradual. In a large number of cases, where the required amount of alteration is not very considerable, the immediate process is preferable, the chance of mischief arising in consequence of the sudden change from a position which may have lasted for a length of time, not being very great if the operation is properly performed, and the after-treatment careful and judicious. In many instances, however, the restoration of shape can be better effected gradually or painlessly by simple mechanical contrivances carefully adapted to the individual joint, and in such cases this plan of treatment may properly be adopted. (See the essay on ORTHOPÆDIC SURGERY.) If immediate reduction is determined on, it is desirable that the surgeon should have a clear notion of what he is about to do; that he should have determined the position to be chosen, and calculated the obstacles to be overcome. The key to success in the process of immediate replacement consists in the previous manipulation. When the patient is placed under chloroform, therefore, the movements for the purpose of breaking down the adhesions which have formed should be properly adapted to fulfil their purpose. Instead of applying the force employed simply in one direction, by attempting *at once* to straighten the limb, the first process is to move the joint in every sense so as to render it as supple as possible. Accordingly the limb is to be alternately flexed and extended (or, it may be, abducted and adducted likewise) steadily and gradually with somewhat increasing force, till as much as possible of the natural extent of motion is obtained. When the adhesions are sufficiently broken down, the limb may then be placed, by appropriate traction and pressure, in a proper position, and secured on a splint.

Many cases of ankylosis, it was stated, are complicated by the existence of muscular retraction, which prevents the necessary movements for the relief of the ankylosis. If the existence of this retraction is evident, the muscles may be divided subcutaneously a few days before the main operation. It may happen, however, that a retracted condition of one or more muscles only becomes evident during the manipulation under chloroform. One of two courses may then be adopted. Having restored as much motion as possible to the joint, tenotomy may be practised on the opposing muscles, and the remainder of the operation suspended till the wounds have entirely healed. Or, as M. Bonnet recommends, after subcutaneous section has been practised, the movements may be persevered in till restoration of the articular functions is effected to the greatest practicable extent. If the latter plan is adopted, a very long but fine tenotomy-knife should be employed, and the integuments punctured at a considerable distance from the point of section of the muscle, to avoid if possible the risk attendant on the admission of air to the cut surface during the movements which are being performed.

As the effects of chloroform pass off, the pain which is experienced may be expected to be severe for some hours, but speedily subsides, without the development, usually, of any very severe inflammatory symptoms. Constant irrigation of the joint may be practised for the first day or two in the manner described in a preceding section, the limb being effectually secured on an open splint (the plan I usually adopted at the Hospital for Sick Children); or the whole limb may be wrapped in cotton wool, and the bandage at once starched, as recommended by Bonnet. When the proper direction has been restored to the ankylosed limb, and any inflammatory symptoms produced by the force employed have subsided, it is time, if the case is one which allows of any hope of success, to adopt such measures as may tend to develop renewed mobility of the joints. For this purpose, baths and friction may be employed, and steady and judicious passive motion had recourse to, which may be performed by the hand (usually sufficient in the child); or still better, in the adult, by various mechanical contrivances, which could hardly be understood from any verbal description.

In estimating the chances of success from these proceedings, the age of the patient and the duration of the lesion are mainly to be considered. In youth, and especially in childhood, at an age, that is, under sixteen, assuming the constitutional condition to be good, the results are usually favorable. In middle life, there is still a fair hope of success, or at least of much improvement. Beyond this period, however, and as advanced age is attained, the chances are much diminished; and if the lesion is of old standing, if the adhesions have acquired great solidity, or if the ankylosis is complicated with other local mischief, not much hope of benefit can fairly be entertained.

When the ankylosis is *osseous*, the means already spoken of are obviously inapplicable. Supposing the position in which the ankylosis has occurred to be inconvenient, it has been proposed by Dr. Barton, of Philadelphia, to remove a wedge-shaped portion of the bone from the projecting surface of the angle formed by the limb; the extent of the broad part of the wedge varying, of course, with the amount of the deformity. When this osseous wedge has been removed, either from the ankylosed part itself, or a little above or below this point, as may be considered expedient, the remaining thickness of the bone is fractured, and the two surfaces brought together so as to redress the angular deformity previously existing.[1]

Finally, cases of ankylosis are sometimes met with in which the limb is not merely useless, but an incumbrance, whilst the continuance of disease in the bones, or the existence of other complications affecting the surrounding structures, prevents replacement from being effected. It may then become expedient to remove the diseased joint, or even the entire limb. The propriety of such operations must obviously depend upon the merits or peculiarities of each individual case.

[Forcible motion is useful not only in joints absolutely stiff from fibrous adhesions, but also where some motion is possible, limited by single or partial adhesions. For the recognition of partial adhesions, according to Wharton Hood, two indications are sufficient, viz., a slight degree of mobility checked by pain, and accompanied by a spot tender on pressure. In such cases a quick forcible movement sufficient to rupture the adhesions is beneficial, while insufficient attempts at forcible movements are injurious, exciting irritation, without removing the source of the pain. The method used by Mr. Hutton, one of the most celebrated of "bone setters," was, according to Mr. Hood, as follows: After thorough examination to determine that no active inflammation was present, a spot tender on pressure, usually on the inner side of the joint, was found. The limb was seized, pressure made upon the tender spot with the thumb of one hand, and the limb forcibly flexed, or flexed and extended, abducted and adducted. The direction of movement should depend upon the direction of resistance. Pulling the limb is of little use in breaking up these adhesions, according to Mr. Hutton, but a rotation or twist appeared to be of service.

---

[1] See also the essay on ORTHOPÆDIC SURGERY, in this volume, for an account of a less severe form of operation recently introduced by Professor Gross.

The affections in which these manipulations are of use, are in joints stiff after a sprain, or after immobilization in fractures near a joint, joints affected by the results of too long continued rest, or the adhesions of periarticular inflammation, or hysterical joints.[1]

Koch reported before the seventh Congress of German Surgeons a hyperæsthesia of the joints, characterized by great pain on moving the joints, but without anatomical lesion in the articulations. This he showed by experiments follows certain injuries to the spinal cord, which may develop not only a hyperæsthesia of the skin, but also of the fasciæ, periosteum, and joints. This followed also injury involving the lateral cerebellar cords, but not injuries to the great nerve-trunks.

In these cases powerful electrical irritation of the skin relieved the pain, but did not effect a cure. Narcotics were of no use.[2]]

ARTICULAR NEURALGIA.

We frequently meet with cases where pains are experienced in the joints without any appreciable material lesion to account for them. In many instances these are termed, and no doubt correctly, rheumatic or gouty pains, for these two conditions may have manifested themselves unquestionably in other articulations, or may ultimately appear in those which have been the seat of the erratic suffering. Occasionally pain gives a brief warning of mischief about to be developed, which it precedes only by a short time. In the pyæmic condition, for instance, a sharp pain may be felt in some joint, and though no other sign of diseased action is present, we are led to expect the formation of matter in this situation, and the progress of events commonly justifies our apprehensions.

The pain may have a local origin, independent of any disturbance in the joint in which it is experienced. The pressure of a tumor on some nervous trunk may give rise to suffering referred to its articular branches; and all surgeons are familiar with the fact, that pain in the knee is one symptom of disease within the hip, and yet this sympathetic affection may so mask the original disease, that I have frequently had children with diseased hip brought to me, in whom blisters or other local remedies had been applied to the knee, under the idea that *it* was the seat of mischief.

Unquestionably, however, the majority of these cases are dependent on that abnormal condition of the nervous functions which is termed hysterical. The condition, indeed, is not absolutely confined to the female sex, as the original signification of the term would imply (ὑστέρα, womb), for it may occasionally be met with in males, though far less frequently than in the other sex. When this morbid condition of the nervous system prevails, a local direction is often given to the perverted sensibility, by some accidental concentration of the "*attention*" on the part. The physiological effects of undue "attention" on organs are of great interest, and serve to explain many curious phenomena exhibited in certain disturbed conditions of the nerve-centres, which may be induced artificially, as in hypnotism, or arise from less obvious internal causes, as in hypochondriasis. I am unable in this essay to devote more space to this subject, but must confine myself to a simple notice of the effects which may be produced by involuntary or automatic "attention." A woman is brought into close relation with some one suffering from cancer of the breast; the attention is directed involuntarily to the corresponding organ in herself; the part becomes painful, swelling even occurs, and what is termed neuralgia of the breast is set up. A case is related of a gentleman who lost

[[1] Bone Setting. Wharton Hood, London, McMillan & Co., 1871; Med. Times and Gaz., April 17, 1880.]

[[2] London Med. Record, May 15, 1878, p. 222; see also Shaffer, The Hysterical Element in Orthopædic Surgery, New York, Putnam, 1880; Jacobi, Am. Journal Obstetrics, June, 1876, p. 218; Paget, Nervous Mimicry, Lancet, Nov. 11, 1873, p. 619; Neurosis of Joints, Berl. Klin. Woch., 1874, No. 26.]

an intimate friend from cancer of the œsophagus: the sufferings which he witnessed made a strong impression upon his mind; he began himself to experience difficulty of swallowing, and ultimately died from the effects of spasmodic dysphagia.

In hysteria, when the attention has been fixed on an articulation from mental or from emotional causes, or in consequence of some slight injury, symptoms which might be supposed to indicate structural disease of the joint are apt to show themselves. There is great *pain;* pain out of proportion to the other symptoms, and frequently extending over a large surface, but often suspended if the attention is diverted, and completely absent during sleep, which may be prolonged and sound. The *tenderness* is also exaggerated, and usually greater in the integuments than in the deeper structures; it is little felt, too, on firm pressure on the articular surfaces effected from a distance. There is sometimes a slight amount of *swelling*, which is diffused in the external areolar tissue, and arises from a turgid condition of the small vessels, or from increased effusion into the areolar interspaces. On handling the part, *fine crepitation* is often felt, evidently situated near the surface, and differing essentially from the grating or crackling which may be attendant on removal of the cartilages. Frequently *convulsive* or *spasmodic action of the muscles* is induced by any attempt to bend or straighten the joint; or sometimes there is a more permanent *rigidity*, by which the limb is fixed in some improper position. When volition is suspended, however, the rigidity and the spasm are suspended likewise. General symptoms indicating hysteria are often present; in many cases there is habitual coldness of the extremities, with other evidence of weak circulation; but articular neuralgia is sometimes seen in stout and florid girls. Some irregularity of the menstrual functions is usually present.

The diagnosis in these cases is generally not difficult, for it is commonly easy to detect symptoms which unequivocally vary from those which would be induced by true structural disease. It may be mentioned, however, that in old cases the patient may have acquired so much information regarding the symptoms which ought to be present, that less chance is afforded to the surgeon of detecting any palpable inconsistency. Where any doubt exists as to the true character of the affection, time should be taken before a positive opinion is pronounced; a careful examination, too, should be made, to detect and remove any local cause of nervous irritation; for these sympathetic pains may be maintained by disturbance of parts with which there is indirect nervous communication, and relief of the one will be followed by cessation of the other.

The general principles of the treatment have been laid down in the essay on HYSTERIA. In most cases tonics and antispasmodics are beneficial. Great attention should be paid to the due action of the skin and liver; and where a tendency to periodicity is present, quinine is of marked service. Change of air and occupation are beneficial, especially residence at the seaside, where salt-water bathing, general or local, can be easily enjoyed. The patient should be urged and encouraged to use the articulation. If the limb is contracted, and any attempt at restoring the joint to its natural position is strongly resisted, chloroform may be had recourse to, and the part maintained afterwards for a *short* time on a splint, with advantage; but exercise of the joint should speedily be enforced. The moral treatment to be adopted is of material importance. The attention of the patient must especially be directed elsewhere, every effort should be made to cultivate the power of "self-control," and healthy occupation given, if possible, to the mental as well as to the bodily functions. A judicious mixture of firmness with kindness must also be exhibited both by friends and surgeon, and the confidence of the patient acquired, which can never be done if any form of deception is had recourse to, as has sometimes been recommended.

INJURIES OF THE JOINTS.

Wounds of Joints.

The joints are liable to various and severe injuries. The ligaments and other soft parts in the neighborhood may be strained or otherwise damaged; the bones may be suddenly forced apart, and their natural relation to each other altered; or a fracture may extend into and implicate an articulation. These injuries, however, have already been described, generally, under the heads of DISLOCATION and FRACTURE, or, as they affect the individual joints, in the essays which treat of injuries in the different regions. The subject of *wounds of the articulations* is the only one that remains, therefore, to be noticed in this place.

In treating of wounds of the joints, I shall confine myself to those in which the synovial membrane is actually penetrated, indicated by the presence in the blood of thin lines or streams of semi-transparent glairy synovia. The wounds may be punctured, incised, or contused. The gravity of a *punctured* wound is influenced to a certain extent by the course which it takes, as well as by the nature of the instrument with which it is inflicted. When oblique in its direction, of narrow dimensions, and made with a sharp clean weapon, it corresponds to the wounds produced in subcutaneous surgery, and has comparatively little tendency to give rise to suppuration; a direct wound, on the other hand, even of the same size, is more prone to produce serious mischief, especially if it is made with a blunt or jagged instrument. To a certain extent, the same observations apply to *incised* wounds, but their greater dimensions much increase the chance of the admission of air, and of the supervention of destructive inflammation, whatever the direction they have taken. *Contused* wounds of a joint may be inflicted from within or from without. The former have been described under the head of Compound Dislocation; the latter are produced by heavy or blunt instruments, and are formidable from the injury of the soft parts they involve, and the consequent chance of mortification, as well as from the inflammation they may be expected to induce.

Under favorable circumstances, the edges of an incised or punctured wound, if maintained in perfect apposition, may unite speedily by the processes described in the essay on WOUNDS, and the articulation be restored to a sound and healthy condition. When the wound is much contused, the edges gaping, or when other circumstances are not favorable, severe inflammation takes place, suppuration rapidly ensues, and destruction of the joint may be expected to occur. The mischief may not even be confined to the articulation; pyæmia may be established; or the patient may sink, exhausted by the profuse discharge, and the fever excited by the local irritation; there is also a risk of tetanus making its appearance.

The causes of the grave character of these lesions are not, perhaps, difficult of comprehension. When early union does not take place, and repair has to be effected by what is called the "second intention," suppuration occurs; but the matter is formed not merely at the divided surfaces, as in ordinary wounds, but extends to, and accumulates in, a large and often intricate synovial cavity, which does not communicate freely with the surface, but allows of burrowing and confinement of the pus, and so favors its decomposition, with the consequent constitutional disturbances. The structure of some of the tissues which form the walls of the cavity is also most unfavorable when suppuration has occurred; instead of being vascular and full of life, soft and able to approximate and contract, the cartilaginous surfaces in the joints are unyielding, and so low in their vitality as to be little capable of efforts at reparative action; even when the cartilages disappear, the osseous structures which are exposed are themselves far less adapted for the process of granulation than the softer tissues, and obliteration of the pus-forming cavity becomes a slow and tedious process, often interrupted by local or constitutional mishaps. Finally, even if repair does not take place, it has been effected at the expense of the functions of the part; for union of the opposing surfaces of an articulation involves ankylosis, and consequent loss of mobility—the purpose for which the joint was constructed.

When a wound exists in the neighborhood of an articulation, it may be of such a size, and have so freely exposed the interior of the joint, that no doubt can exist as to its extent. In certain cases, however, it is not always easy to determine whether the synovial membrane has been injured or has remained intact. We are guided in our opinion by the position of the wound, its direction, the degree of penetration, and the form of the weapon. Our diagnosis may be assisted by the presence in the flowing blood of semi-transparent glairy synovia in thin lines or streams; but the absence of synovia does not prove that the articulation is uninjured (for its escape may be prevented by various circumstances), and its presence is not conclusive in favor of injury, for the fluid may have been discharged from a synovial bursa or from a tendinous sheath. When any doubt exists, researches with a probe had better be avoided, and the case treated at first as if penetration had undoubtedly occurred.

The dangers attendant on a wound extending into an articulation are influenced by several circumstances. In early life such wounds are usually attended with less severity of symptoms than at a more advanced age, and a good constitution is more likely to do well than one which has been broken down by prolonged debauchery. A small joint will escape with impunity where a large one would be destroyed; and even if the articulation is destroyed, the general disturbance may be trifling. The upper extremity is more favorably situated than the lower, as far as the chance of recovery is concerned; and finally, a wound inflicted with a sharp instrument is more likely to unite than one which has been attended with much violence to the softer tissues.

In managing a wound of a joint, it becomes evidently of the highest importance to procure, if possible, immediate union, and prevent the occurrence or check the spread of inflammation. Every wound involves a tendency to inflammatory action; but the smaller the amount which is excited, and the more complete the absence of inflammatory exudation, the better the form of healing which occurs. The size of the wound, and the degree of violence with which it was inflicted, are elements in the production of inflammation over which we have no control; a third element is the duration or amount of exposure to the atmosphere; this is within our reach, and the importance which has long been attached to the prevention of access of air to a wounded joint is fully justified on theoretical as well as on practical grounds.

When there has been much laceration and contusion of the soft parts, little or no chance of immediate union exists. For the description of the management of this class of wounds, however, the reader may conveniently be referred to the essays which treat of Gunshot Wounds and of Compound Dislocations; for contused wounds of joints usually fall within one or other of these two categories. In punctured or incised wounds, if seen at a sufficiently early period, the treatment is directed to procure rapid union, and prevent the occurrence of inflammation, or reduce it to a minimum. For this purpose, we retain the wounded surfaces in close apposition, and adopt such measures as will ensure perfect immobility of the joint, whilst we exclude all exposure to the air. If any foreign or detached body is present—a piece of glass, for instance—it is carefully removed, and the wound, having been gently cleaned and thoroughly washed with a solution of carbolic acid, must then be closed effectually and its surfaces, for their entire depth, kept in close and steady apposition. [A description of the treatment of wounds of the joints, according to antiseptic principles, belongs properly to the subject of Antiseptic Surgery. It may be mentioned, however, that in case of direct opening into a joint, it is essential to secure, first, good drainage for such fluid as may accumulate; and, second, to prevent putrefaction of the discharges by syringing out the cavity with antiseptic fluid, and the application of an antiseptic dressing.] The mode of effecting this must vary; where only a small puncture exists, it may be sufficient to apply a piece of lint, which may be soaked in carbolic oil or blood, or covered with collodion; if the wound is of some extent, something more is required; on the whole, sutures are preferable to adhesive plasters, being less liable to be disturbed, and admitting of the application of moisture to the part; the twisted suture appears to be the most efficient, as it maintains the divided surfaces in contact to a considerable depth. The wound may then be protected from the air by a covering of stout tin-foil, previously washed with the solution of carbolic acid, and nicely adapted to the surface, this being again covered by a rather larger piece of lac plaster charged with carbolic acid, and a fold of lint dipped in carbolized oil (as described by Mr. Lister) applied over the plaster and renewed, by being moistened with the oil, once at least in twenty-four hours; the under-dressings, of course, not being interfered with unless it becomes absolutely necessary to do so. The limb must be carefully secured on a splint, or otherwise fixed in that position which will be most advantageous to the patient should rigidity ultimately occur. As perfect immobility is of the greatest importance, the splint must be carefully selected, so as effectually to prevent any articular movement. The immediate and continued application of cold to the part, in the form of irrigation or of iced water in vulcanized India-rubber bags, is usually attended with great advantage in preventing or subduing inflammation. The general treatment, at an early period, should be moderately antiphlogistic, without permanently lowering the strength, great demands on which may be expected should events take an unfavorable direction. Care should be taken not to disturb the antiseptic dressings so as to allow the wound to be unprotected by them, and the sutures may be left with advantage for many days, perhaps a week, or so long as there is any hope of union being obtained, unless their removal is required to give exit to matter.

In spite of the measures adopted, or in consequence of the case coming too late under treatment, inflammation may run high and suppuration occur. When matter has unquestionably formed, any attempt at union is abandoned, and free exit afforded to the pus, either by enlarging the original wound, or, if necessary, by making free incisions in a more depending position; but an attempt may still be made to arrest decomposition of the matter by the continued use of antiseptic dressings. The further progress of the case does not differ materially from that already described under the head of Suppuration in Joints (see p. 242), to which the reader is consequently referred.

[As is well known, dangerous symptoms frequently follow punctured wounds of the joints, but cases are sometimes met where wounds of this character heal without trouble. This is not only true of large openings made by cuts through the ligamentum patellæ with an axe or scythe, but also of small penetrating wounds.[1]

[[1] See Alfred Hosmer, Boston Medical and Surgical Journal, April 17, 1879. Six cases

How frequently evil results from wounds to the joints follow, and when immunity from surgical fever is to be expected, it is impossible to say.

Pirogoff saw in the Crimean war only three recoveries from shot wounds of the joints after suppuration had occurred.

Bergmann, in the late Turko-Russian war, out of fifty-nine wounds of the knee-joint saved thirty under a non-antiseptic treatment. Amputation was, however, necessary in two of them.

The results of injuries to the large joints during the war of the Rebellion have not been as yet published. Out of seventy-two cases of gunshot wounds penetrating the shoulder-joint, without osseous lesion, six died (two from pyæmia), thirty-six recovered with stiff joints, thirty were returned to duty. (Surgical History of the War of the Rebellion, Part II., Surgical Volume, p. 502.)

Pirogoff, however, met with five recoveries from incised wounds of joints without suppuration[1].

For exact rules of treatment in joint diseases we must wait until exact diagnoses of the pathological changes can be made. It is manifest that a chronic synovitis, a tuberculous epiphyseal osteitis, and a peri-articular inflammation should be treated at their earlier stages on different principles. The indications for treatment vary also in the different joints according to their anatomical relations, whether surrounded by powerful muscles or superficial; whether needed in locomotion or not. Certain facts, however, are self-evident: if severe pain is caused by jarring a diseased joint, it should be protected from jar; the patient's general condition needs in a chronic affection lasting through years all influences for improving his health, of which the most important is exercise; motion increasing a synovial inflammation should be avoided, as well as a long disuse of a part whose normal condition is use. Reflex muscular contraction is an indication requiring in certain joints, for the future usefulness of the limb, almost as careful treatment as the original lesion. It has been a practice to treat all diseases of joints as fractures would be treated; *i. e.*, by complete fixation until the limb is well, forgetting that a fracture necessitating immobilization for a year would secondarily cause nearly as much uselessness resulting from treatment as that made by the original break.

Verneuil recently expressed his opinion that absolute rest in itself never gives rise to false ankylosis, and that the stiffness following fixation is not the result of changes in the joint caused by the want of motion, but of inflammation checked eventually by rest, but not until certain changes in the peri-articular tissues were brought about. Whether firm adhesions ever follow complete fixation or not may be a question; but it is certain that stiffness takes place, and the period comes when motion is essential to the health of the joint. The problem of the treatment of chronic joint-disease consists in allowing protected motion when the activity of the arthritic inflammation does not demand absolute fixation.

The benefit derived from extension in certain joint affections has been variously explained. It has been regarded as a means of, 1, separating the diseased bones of a joint; 2, of overcoming the spasm of the muscles around the joint; 3, of fixing a joint.

In certain articulations extension certainly separates the bones, as in the finger-joints; in others, as the hip, the bones are not separated by any force which can practically be applied if the capsule is in a normal condition.

Schultze found that the immediate effect of extension on a joint, both knee and hip, filled with fluid, was an increase in the interarticular pressure. After extension was prolonged for a while (seven or eight days) there was a diminution, due either to the relaxation of the ligaments, or to an absorption of the fluid from an increase of the interarticular pressure.[1]]

PART II.

DISEASES OF INDIVIDUAL JOINTS.

The limited space at my disposal requires that any observations I have to offer respecting the peculiarities presented

---

of wounds of the Knee-Joints. For results of antiseptic treatment of Wounds of Joints, see Cheyne, Brit. Med. Journal, Nov. 29, 1880. Eleven cases Wounds of Joints successfully treated, and twenty-one cases of successful operation on Healthy Joints; Wolberg, Berl. Klin. Wochenschr., No. 47, Nov. 22, 1880, p. 668.]

[[1] Wolberg, loc. cit.]

Journ., Jan., 1878; Stillman, New apparatus for extension, London Med. Rec., Oct. 15, 1880, p. 395.]

by disease as it affects individual joints should be extremely brief.

Diseases of the Hip.

Lesions of the hip have attracted especial attention from the importance of the articulation involved, the depth at which it is situated, the mass of soft parts which surround it, and the little leverage afforded by its upper attachment in the pelvis. At the same time, unfortunately, disease of this joint is met with only too frequently, and constitutes one of the most troublesome lesions to which the human frame is liable.

As in other joints, the structures in which disease for the most part commences are the synovial membrane and ligaments and the articular extremities of the bones. Mr. Aston Key was of opinion, from the amount of mischief which is sometimes found in the ligamentum teres at an early period of the disease, that this was the part in which inflammation usually commences. At any rate, there is reason to believe that the ligaments (including the capsule) are often among the earliest structures to be affected.

Acute arthritis of the hip, whether occurring primarily, or in the course of chronic disease, is very serious and often fatal. The symptoms are usually unmistakable, and if matter forms, as is often the case, it should be evacuated early, and antiseptics freely used. The expediency of amputation or excision must be judged of by the circumstances attendant on each individual case.

Common synovitis, as a primary affection, is less frequent in the hip than in the superficial joints; though when it occurs, its symptoms are usually severe, and the suffering experienced considerable.

Morbus coxarius; strumous synovitis and ostitis.—The disease of the hip which is most common, and which is so often met with in early life, is chronic or strumous inflammation, sometimes commencing in the synovial membrane or ligaments, but frequently, also, in the articular extremities of the bones. In retaining the term *strumous*, however, we must bear in mind that, as already stated, it by no means follows necessarily that there is a special tendency to tubercular deposit in the joint or in any other part of the body, or that such general cachexia exists as will prevent reparation of the local mischief. If attention to the general health is *desirable*, attention to the local treatment (especially in the form of securing the joint in a most perfect state of rest), is *indispensable*, and any neglect of it on the part of the surgeon hardly admits of excuse.

It is of great importance to recognize chronic hip-disease as early as possible, before permanent mischief has occurred. The first symptoms to be noticed are, a slight limp in walking, with disinclination to bear the whole weight of the body on one particular limb; if attention is now carefully drawn to the patient, the thigh will probably be found to be slightly flexed on the abdomen, and a certain amount of feverishness may be noticed towards evening, after a day's exercise, with a little restlessness during the night, accompanied, perhaps, with slight occasional twitches or jumps of the thigh, which will usually be somewhat flexed and adducted during sleep. If a careful examination of the hip is now made, it will be found to be held a little stiff, and some pain will be evinced on moving the joint or on pressing the articular surfaces together, either directly at the greater trochanter or front of the joint, or indirectly through the foot.

If these symptoms are not attended to, and the disease proceeds a stage further, the lameness becomes very marked, the limb will be found apparently altered in length, flattening of the nates will be detected on examination, and very decided pain will be complained of. The causes of the apparent alteration in length are mechanical. The thigh is flexed on the pelvis, but combined with this flexion, which is very seldom *simple*, are two principal deviations; in the one case we find inclination and rotation *outwards*, attended with apparent elongation of the limb; in the other, there are inclination and rotation *inwards*, producing apparent shortening. Now, supposing the femur to be bent at an angle on the pelvis, and the foot turned out, when the patient tries to stand or walk the weight of the limb has to be supported, but in order that the foot may reach the ground, that side of the pelvis is depressed and advanced in front of the other; in this way the limb *appears* to be elongated. In the opposite condition of flexion combined with adduction and rotation inwards, the corresponding side of the pelvis, for a similar reason, is raised and carried backwards; a position which involves apparent shortening when an attempt is made to place the limbs parallel with one another. The position which is recommended as best suited for examination is that in which the trunk and the *sound* limb are perfectly straight: the nature of the alteration, as it affects the diseased side, is then more evident than if the two thighs are placed parallel.

The fixed and altered direction of the affected extremity soon entails secondary deformity in other parts, especially in the spine. When the thigh is fixed at an angle with the pelvis, in order that the weight of the extremity may be supported, the pelvis itself becomes inclined forwards; to compensate for this inclination and maintain the balance of the body, the vertebral column is strongly curved, producing a deep hollow in the lumbar region, with corresponding projection of the abdomen anteriorly. The exact nature of this secondary deformity is readily seen, either in the recumbent or in the erect posture, on supporting the affected limb at the angle which it has assumed, when the pelvis and spine may easily be restored to their natural direction. Lateral deviation of the spine may also be induced, to compensate for the lateral inclination or twisting of the pelvis. The pelvis, it will be noticed, shifts or alters its position; and, indeed, increased mobility of the pelvic articulations often occurs to an extraordinary extent, especially in the later stages of hip-disease, when recovery is taking place, with ankylosis or rigidity of the hip itself. In such cases, in early life, the amount of motion which becomes developed at the sacro-iliac synchondrosis and other neighboring joints may closely imitate the natural mobility of the hip, and easily deceive a careless observer.

The condition of apparent shortening frequently follows that of apparent lengthening, though it may occur where no lengthening has ever manifested itself. Is there ever any *real* alteration in length? Though many causes have been advanced which might give rise to actual elongation of the limb, it is hardly probable that any of these should actually occur, and it may be said that the lengthening is, in truth, only apparent, depending on the altered position of the pelvis. In the early stages of hip-disease the same observation holds good with respect to the opposite condition. In other cases, however, a certain amount of genuine shortening really does take place. When the osseous structures are involved in the disease, the spasmodic contraction of the muscles maintains constant pressure of the head of the femur on the upper part of the acetabulum; if this is already softened, and the cartilages ulcerated or absorbed, the border or edge of the acetabulum yields to the pressure, it becomes deeply ulcerated and excavated, and the head of the femur itself, which has been more or less disintegrated, is drawn up into this excavation, which is enlarged to receive it, in the direction of the external iliac fossa. This condition constitutes what has been termed *spontaneous dislocation* from disease, which differs evidently from traumatic dislocation, in which the head of the femur clears the rim of the acetabulum, which remains intact. When this false or incomplete luxation has occurred, the trochanter major will be found to be displaced upwards, and a certain amount of real diminution in the length of the limb will be present, increased, of course, if the head of the femur is destroyed to any extent. In some cases, however, *true* luxation from disease actually occurs, as may be seen in the accompanying illustration, taken from a preparation in the Museum of St. George's Hospital, in which the head of the femur is situated very near the ante-

Fig. 670.

Dislocation of hip from disease. (From a preparation in the Museum of St. George's Hospital.)

rior superior spine of the ilium. In very exceptional cases, too, the head of the femur is forced through the acetabulum, so as to enter the pelvic cavity.

Another, and a very striking change, which will be found at a comparatively early period, consists in a certain amount of alteration in the fulness of the nates. These are often flattened and appear wider than natural. This alteration depends partly on wasting of the gluteal muscles from want of use, partly, also, in the position of abduction, on the twist of the pelvis and consequent diminution in the projection of the tuber ischii.

The pain which is experienced is not confined to the hip, but is often referred to the inner side of the knee. It is due probably to pressure on, or irritation of, the branch of the obturator nerve distributed to the capsular ligament and ligamentum teres, referred sympathetically to the terminal cutaneous branches of the same nerve. In the same way, if the articular branches of the anterior crural or sciatic nerves are more particularly involved, we may find the pain referred to the front or outer side of the knee, or even to the heel or ankle. From whatever cause it arises, this pain is sometimes the first symptom which attracts attention, and may lead to mistakes regarding the real seat of the disease. The chance of error is increased if puffiness over the knee accompanies the pain, as it does sometimes; just as swelling of the testicle may be produced by the passage of a calculus along the ureter, from pressure on the spermatic plexus, and consequent nervous disturbance of the nutritive conditions of the parts supplied by its peripheral branches.

In the third stage of hip-disease, all the symptoms are much aggravated. The starting pains are very violent, rendering the nights much disturbed. The limb is still more distorted, and real shortening is often present from the incomplete luxation already described. There is much fever, with increased local heat; suppuration has now taken place, and crepitus may be detected when the articular ends of the bones are moved on each other. When abscesses form, they may point in almost any part of the limb, either in the vicinity of the joint, or after having burrowed among the muscles to a great extent, especially when the erect posture has been long maintained. If the sinus is situated some distance down the thigh, near the inferior attachment of the tensor vaginæ femoris, the probabilities are in favor of the femur being the seat of mischief. When the acetabulum has originated or participated in the disease, and matter has formed in the pelvis, the abscess often shows itself at the outer part of the groin in the neighborhood of the antero-inferior spine of the ilium; occasionally it passes down by the rectum, into which it may burst, or it may reach the surface close to the anus.

[Hip-joint disease may also be confounded in the early stage with sacro-iliac disease and osteitis of the great trochanter, and inflammation of the trochanteric bursa.

Verneuil mentions a contraction of the adductors of the thigh which simulated hip disease in many respects. This affection is almost always bilateral.[1]

Synovitis of the hip-joint of a subacute

[[1] L'Union Médicale, Sept. 8, 1877, p. 373.]

and chronic character is probably not as rare in the hip-joint as has been supposed.[1]

Pain cannot always be relied upon as a certain diagnostic symptom in the initial stage of hip-disease, or aggravation of the pain when the limb is pressed upward. Limping in gait, and stiffness or limitation to motion, are the earliest symptoms; atrophy and diminution of the electrical contractility are also early symptoms of psoitis which may be confounded with hip-disease.[1]]

Fig. 678. The same case with pelvis horizontal and leg adducted.

There are one or two points in the diagnosis to which I may briefly direct attention. I have seen congenital dislocation mistaken for hip-joint disease, and the child subjected to much unnecessary confinement and suffering. A little attention readily distinguishes the two affections. The history of the case, and the existence of evident limping from the first moment when any weight was allowed to rest on the limb, the absence of pain, and the extent of real shortening, aggravated when the limb is pressed upwards, diminished when extension is made, are symptoms of congenital dislocation which differ widely from those which would have been presented by severe disease of the joint. We occasionally meet with cases in which a difference in the length of the two lower limbs exists, resulting in some instances from congenital malformation, in others from infantile paralysis, which has led to wasting and defective growth of one extremity. Such a condition, if existing to any extent, causes limping in the act of walking, and leads to secondary deformity of the spine, in the form of lateral curvature, to counteract the tendency of the body to fall towards the affected side. This state might easily be mistaken for diseased hip, as well as for diseased spine, until a careful examination of the whole limb is instituted, when the cause of the symptoms is readily detected.

[Fig. 679.

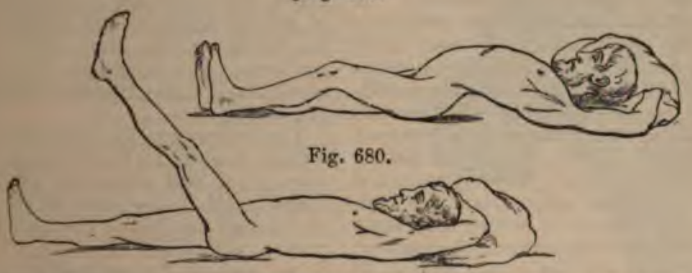

Fig. 680.

Fig. 679. Lordosis of spine caused by hip-joint disease. Appearance in recumbent posture.
Fig. 680. Lordosis effaced by elevating the flexed leg.]

Psoas abscess, with or without disease of the spine, may be mistaken for hip-disease. A case of this kind, where the psoas abscess was connected with extensive tubercular disease in and around the kidney, came under my care at the Hospital for Sick Children, which had been considered and treated previously as disease of the hip. The limb, in such a case, may be flexed on the pelvis, and any attempt at extension give rise to great suffering; it will be found, however, that, provided the psoas muscle is kept relaxed and no traction upon it allowed, free movement of the joint may be effected,

---

[[1] Nicaise, Diagnostic des Maladies de la Hanche, Thèse de Paris, 1869; Gibney, Am. Journal Med. Sc., Oct., 1878, p. 383; Morgan, St. George's Hospital Reports, vol. x.; Coxitis Hæmorrhagica, Allg. Med. Cent. Zeitung, Dec. 19, 1877.]

[[1] Thèse de Paris, 1877, No. 526; Œster. Jahr. f. Pædiatrik, viii., p. 177.]

and its articular surfaces rotated on one another or pressed together with much force, but without suffering. The situation of the abscess, also, serves to assist in the diagnosis, for pelvic abscess, depending on hip-joint disease, is almost invariably complicated with sinuses in other situations. Inflammation of the bursa under the psoas-iliac may simulate hip-disease, and be with difficulty distinguished from it. Sometimes, indeed, the bursa communicates with the joint, and disease beginning in one involves the other in its course. If such is not the case, and the inflammation is confined to the bursa, there will be pain and tenderness on pressure at the front and inner part of the joint, with, it may be, some indistinct swelling in that situation; the mass of muscles, however, obscuring the bursal tumor. The limb is usually instinctively flexed on the pelvis, as in hip-disease, and any attempt to extend the limb, or any movement which involves traction on the psoas muscle, is attended with suffering. The diagnostic marks correspond to those just mentioned. If care is taken to avoid any pressure on the bursa, or action of the psoas, the joint may be freely handled without suffering; moreover, no tenderness or swelling can be detected behind the trochanter.

The treatment of strumous disease of hip does not differ materially from that already recommended for strumous inflammation of the joints generally. If detected at the earliest stage, complete rest of the joint, at first in bed, afterwards by means of a splint, which must be long enough to secure perfect immobility of the hip, will be sufficient. But the rest must be continuous and maintained for an adequate period, the general health being at the same time properly attended to. In the second stage, when the limb is apparently altered in length and some starting pains have manifested themselves, confinement to bed for a long period is necessary, and extension by means of weights, to relieve the muscular spasm, may be used in the way already described. If the thigh is flexed and adducted, it must be straightened, which can be done readily enough under chloroform when the disease is recent, and with care and caution even at a later period when adhesions have taken place.

When suppuration has occurred, if the symptoms are not very urgent, it is usually better to abstain from opening the abscess, as absorption may be expected occasionally to take place. If there is great pain, and the matter is too deep-seated to be reached conveniently, relief is sometimes obtained, temporarily at all events, by a few lines of the actual cautery. If the pain and distress are still very great, an opening may be made either with a knife or a trocar. In some cases where it is necessary to let out deep-seated matter, in order to avoid a large vessel, the mode recommended by Mr. Hilton may be employed, viz., after making a small incision through the superficial structures, to force a probe-director through the soft parts into the cavity of the abscess, and when pus flows along the groove of the director, to introduce a pair of fine dressing forceps into the abscess, and enlarge the opening by forcibly separating the blades.

If the case has gone on unfavorably, the bone become carious, and extensive suppuration taken place, resulting in sinuses, the health suffers, and the only chance of recovery, or even of preserving life, may consist in excision of the head of the femur, or removal of the diseased bone. Such an operation, in children at any rate, is more formidable in imagination than in reality, and I have had occasion to perform it without any injurious consequences. The subject of excision, however, has been treated of in a separate essay.

[The proper treatment of "strumous disease of the hip" is at present one of the vexed subjects in surgery; the line of treatment customary in some localities being diametrically opposed to that in vogue in others.

In disease of the hip-joint the muscles about the joint play an important part in the production of deformity, and in the increase of the destructive change in the bone. It is in disease of the hip-joint particularly that extension appears to be of great service.

The indications for treatment demand a protection of the limb from jar, and the prevention and correction of deformity. Certain authorities insist on the necessity of absolute fixation of the limb for a long period, while others claim that, if the limb is so placed the muscular contraction and spasm are overcome and jar to the limb is prevented, motion to a limited extent is not injurious except during acute attacks, when the patient instinctively avoids all movement. Excellent results have been gained by the latter method, which has the merit of permitting locomotion.

What has been termed the "American Method," is based on the value of extension. The limb is secured firmly by strips of adhesive plaster, a splint, reaching from the hip and bent below the foot, capable of being lengthened by a key and ratchet, is applied with a perineal strap to secure counter-extension; extension is regulated by lengthening the splint to the bottom of which the adhesive plasters holding the leg are secured. The patient is confined in bed during the painful stage, but is allowed to move about at other times, standing upon the splint, which, being longer than the limb, and bent under the foot, bears the weight of the body, the perineal strap preventing the patient from sinking, and touching the floor with his heel. The sound foot is raised, to keep the pelvis even. When thorough extension is applied, but little motion is possible at the hip-joint, and the joint is more thoroughly fixed than would be supposed, so much so that some surgeons believe that the chief benefit from the apparatus is gained from the fixation thereby afforded. Different appliances have been devised and are used, but all are based on the principle of extension.

For the purpose of absolute fixation the gouttière of Bonnet, modified and improved by Bauer and Sayre, enables the patient to be carried about, but does not allow locomotion. To gain this, Mr. Thomas's apparatus has been used extensively in England, and has the advantage of cheapness and is easily applied. The fixation furnished by it is not as complete as that given by the gouttière.

Dr. Hutchison has lately introduced what he terms the physiological method. The patient is furnished with crutches and is allowed to walk about freely; the sound limb being raised by a high sole, and the affected limb allowed to swing. The weight of the limb is supposed to furnish sufficient extension, and fixation is secured by the physiological action of the muscles about the hip. In cases during the painful stage, the patient is confined to bed temporarily, and extension is secured by a weight attached to a cord passing over a pulley and attached to adhesive plaster applied to the limb. Hutchison's method is yet sub judice, and apparently answers in some light cases, but it is certainly not suited for all or the average cases of hip-disease.[1]]

Morbus coxæ senilis.—In advanced life another form of disease is apt to occur in the hip, which is known by the name of the *morbus coxæ senilis* or *chronic osteo-arthritis.* Unlike strumous inflammation, this disease seldom occurs under the age of forty, and often appears as a local affection, without any visible impairment of the general health. In chronic arthritis of the hip, there is stiffness of the articulation, and a certain amount of dull pain extending down the *front* of the thigh; the pain, however, though augmented after much exercise, diminishes during the night, and is not increased even by rough pressure of the articular surfaces against one another. The mobility of the joint is much interfered with, and a loud crackling can be distinctly heard when the limb is exercised. When the disease is well established, the foot is much everted, the nates are flattened, and there is *apparent* shortening of the extremity to a very considerable extent, in consequence of elevation of the corresponding side of the pelvis; a certain amount of *real* shortening may also take place after a time, from the changes which occur in the femur, the head of which may become altered in shape, and flattened, whilst the neck may assume a horizontal direction, so that the upper extremity of the bone may be placed below the level of the trochanter major. At this stage of the disease, too, bony protuberances may perhaps be felt around the articulation. The characters enumerated are so distinct from those of strumous disease of the hip, that mistakes between the two can scarcely arise. From sciatica it is distinguished by the character and situation of the pain, as well as by the presence of shortening of the limb, real or apparent, and eversion of the foot. The appearances presented somewhat resemble those of fracture of the neck of the femur, for which it might possibly be

mistaken if any injury or accident had previously occurred. The history of the case, however, and the slow and gradual progress of the symptoms, as well as the osseous growths which are apt to form, are sufficient for accurate diagnosis. Where constitutional symptoms are present, the disease extends to other and smaller articulations, and the character of the affection cannot fail to be recognized.[1] The treatment of this affection is noticed in the section on Chronic Rheumatic Arthritis.

Neuralgia of the hip.—This joint is frequently the seat of hysterical pain, closely simulating structural disease. The diagnostic characters of this affection have already been pointed out (see Articular Neuralgia). It may be remarked, however, that apparent shortening of the limb may be present in these cases, owing to alteration in the direction of the pelvis and its relation to the vertebral column, induced by long continuance in one unnatural posture. Lateral curvature of the spine also is frequently noticeable; but the nates are not flattened, and abscesses do not form.

Diseases of the Pubic, Sacro-iliac, and Sacro-coccygeal Joints.

These articulations, in consequence of their anatomical arrangement, are less exposed to disease than the proper diarthrodial joints of corresponding size.

As a consequence of hip-disease, especially in early life, the pelvic articulations become unusually movable; to such an extent indeed, that rigidity, or even complete ankylosis, of the diseased hip-joint may be attended with but little loss of the mobility of the limb.

Disease of the symphysis pubis is very uncommon.

A case, however, of extensive ulceration of its fibro-cartilage, with superficial caries of the articular surfaces of the contiguous bones, accompanied with a large abscess in the sheath of the rectus, occurring in a female, will be found in the fifth volume of the Pathological Transactions. Dr. Humphry also quotes a case related by Otto, in which the symphysis, as well as the right sacro-iliac joint, were completely ossified in a middle-aged woman. Two other cases of ossification are also referred to, but ankylosis is undoubtedly very rare.

Acute inflammation of the sacro-iliac joint may result directly from injury. A case is related by Louis in which a sack of corn fell on the loins of a man who was stooping at the time. The accident gave rise to some swelling of the part, followed after a time by violent pain and much febrile disturbance, and death ensued at the end of the twentieth day. Very extensive inflammation, attended with suppuration, was found in the right sacro-iliac articulation, and the bones were separated to a certain extent from one another.

Disease of the sacro-iliac joint may arise in connection with pregnancy or parturition. During pregnancy the union between the pelvic bones is said to become less firm, and in certain cases the relaxed condition of the sacro-iliac joint is so considerable as to give rise to pain, as well as to difficulty in standing or walking; during exercise, too, the patient may be sensible of a certain amount of motion between the sacral and iliac bones, and sometimes a distinct "crackling" can even be heard. In most of these cases the ligaments resume by degrees their normal condition, and the pain and limping gradually subside. Occasionally, however, the relaxed condition may last for a considerable period, and the limping may continue for months or years, or even, according to Ludovic, for the remainder of life. It may happen, too, that actual inflammation of the joint is set up; the pains become violent; there is swelling about the part; and if suppuration takes place, the case is most likely to terminate fatally.[1]

Sir B. Brodie relates the case of a married lady who was unable to walk without crutches, and who experienced pain after taking exercise, referred to the right groin as well as to the right sacro-iliac articulation, where a projection existed, as if the ilium had been displaced and drawn upwards; the affected limb was two inches *shorter* than the sound one. Pains resembling sciatica had been complained of for many years, but the first distinct symptoms of the affection appeared to be referred to her pregnancy, four years previously. Recovery took place, though the limb remained permanently shortened. Mr. Hilton also relates a case of sacro-iliac disease, occurring after parturition, attended with suppuration within the pelvis, in which the abscess subsequently became absorbed, and a cure was ultimately effected after prolonged mechanical rest.

The chronic form of *sacro-iliac disease* is often traceable to some local injury, though Mr. Erichsen (to whom we are indebted for a very excellent description of this affection) considers it to be usu-

[[1] Senile alterations in joints; arthritis deformans. Weichselbaum, Allg. Med. Centr. Zeitung, March 15, 1878.]

[1] See Desormeaux, Sur les Relâchements, Écartements, etc., des Symphyses du Bassin.

ally strumous in its origin. The symptoms consist mainly in pain in sitting and standing, or even lying on the affected side, as in any of these positions the weight of the body tells upon the inflamed part. The pain may be localized by direct pressure on the affected joint, or by pressing the bones together or the sacrum forwards, and in many cases a little puffiness with some elevation of temperature may be detected in the sacro-iliac region. Frequently, however, as Mr. Hilton points out, the actual seat of the disease may be masked by the pain being referred (through the nerves in relation with the joint), to the hip, knee, or back part of the calf, whilst the psoas muscle may be kept spasmodically contracted from nervous irritation, giving rise to a flexed condition of the hip. There is an absence, however, of any increased warmth in these parts, and by taking care to keep the pelvis quite at rest, the other joints may be moved freely without producing pain. When suppuration takes place, and in most cases it only does so at a late period of the disease, the matter may point posteriorly in the immediate neighborhood of the articulation, or may extend outwards to the great trochanter, or upwards to the loin; if, on the other hand, the matter accumulates in front of the joint, it may pass into the perineum or even open into the rectum, or it may leave the pelvis by the great sciatic notch and point in the gluteal region.

The affections with which sacro-iliac disease is most likely to be confounded are diseases of the hip and spine, but by careful attention to the points indicated, the real seat of the mischief can generally be made out satisfactorily, except, perhaps, when the disease is situated at the junction of the last lumbar vertebra and sacrum, and affects mainly one side.

When sacro-iliac disease is in an advanced stage, and especially when matter has formed to any extent, the prognosis is by no means favorable. In an earlier stage, however (and hence the importance of accurate diagnosis), a cure may not unreasonably be expected, as Mr. Hilton relates several cases, occurring at varying ages, to show that by giving perfect and prolonged rest in the recumbent position, and by steadying the pelvic bones by means of a strong and broad belt so as to favor ankylosis, recovery will often take place.

[Sacro-iliac disease was first mentioned by Boyer in 1821, and later attracted the attention of a number of French observers. The disease is uncommon, but probably more common than is supposed. The most prominent symptom is lameness; the buttock is often flattened, and the thigh and leg emaciated. Local swelling is an early symptom, but it is not always present. Abscess only appears at a late stage.

The affection appears to be most common in adults, but Poore has reported two cases occurring in children aged, respectively, four and five. Out of fifty-eight cases, collected by Poore, recovery was reported in twenty-three. Le Dentu mentions a case following gonorrhœa.

The diseases with which it is liable to be confounded with are :—

Sciatica.
Lumbago.
Psoitis.
Hysterical coxalgia.
Caries of the spine in the lower lumbar region.
Coxalgia.

Characteristic of sacro-coxalgia are the following symptoms: a peculiar projection of the affected side when the patient stands, avoiding pressure upon the inflamed articulation; tenderness over the sacro-iliac articulation; free motion at the hip-joint if the pelvis is fixed, provided no pelvic abscess is present; pain on pressure of the iliac bones together. At an early stage of the disease flexion of the thigh or lordosis is not present. Walking is more painful than in hip-disease, and there is greater relief from rest. Pain along the thigh may be present, but pain referred to the knee is wanting; the point of the foot is not turned from the median line, *i. e.*, no eversion or inversion is present. Nocturnal pain is absent.[1]]

Disease of the sacro-coccygeal joint is occasionally met with as the result of injury, and, for anatomical reasons, more frequently in females than in males, in early life than at an advanced age. The symptoms, as described by Mr. Hilton,[2] are tenderness with increased heat about the joint; pain on defecation as well as on rising from a seat or sitting down, and on walking or running rapidly, the pain in these movements being caused by the action of the corresponding muscles attached to the coccyx. There is also pain on direct pressure on the joint, and on moving the coccyx when grasped between the thumb and the forefinger introduced into the rectum. Rest in the recumbent position, and the prevention of constipation by appropriate diet and the use of laxatives, constitute the treatment recommended.

---

Monthly, May, 1878, p. 81; Pooley, N. Y. Med. Journal, Sept., 1878, p. 314.]

[2] Hilton, On Rest, p. 424.

It may be remarked that symptoms very nearly resembling those mentioned are often met with in hysterical females. In these cases, however, the temperature about the part is not increased, and there is an absence usually of pain when the coccygeal bones are moved in the way previously described.[1]

Diseases of the Knee.

The diseases of the knee have been studied with extreme care, owing to the frequency of their occurrence, as well as to the size and accessible position of the articulation.[2] Hence it is that the affections of this joint are often taken as typical of articular disease generally. The knee is liable to the various morbid changes which have been described in the first part of this essay; to one of them, indeed—chronic inflammation of the articular extremities of the bones—it is specially exposed, for *local abscess* is more common in the head of the tibia than in any other situation; and necrosis of the lower end of the femur is often met with, at first simulating, but subsequently inducing, suppuration of the joint.

The position which the limb habitually assumes in severe disease of this articulation, whether simply inflammatory or strumous in its origin, is one of considerable flexion, frequently combined with torsion, in consequence of eversion or inversion of the foot. If the ligaments become extended or destroyed in the progress of disease, the spasmodic contraction of the flexor muscles acts upon the head of the tibia, which it tends to dislocate backwards into the popliteal space. In our treatment, therefore, we have to guard against this tendency; the foot must be supported to prevent torsion, the limb must be maintained uninterruptedly in a nearly *straight* position, and extension by weights may be used as in the case of hip-disease.

In *chronic osteo-arthritis*, the knee-joint soon acquires a strong inclination *inwards*, whilst the tibia is usually rotated outwards and the foot everted. At a more advanced period, if the limb becomes rigid in a semi-flexed position, the patella is occasionally found resting on the outer condyle of the femur, or even completely dislocated outwards. The amount of synovial effusion is considerable in the earlier stages of the disease, and the swelling will often be found to extend to the popliteal space in the direction of the inner head of the gastrocnemius, owing to distension of the bursa which exists in this situation, and which frequently communicates with the joint. As the disease advances, the patella becomes increased in breadth, and ossific deposits may be distinguished at the condyloid margins of the femur and on the head of the tibia. Pendulous excrescences, or completely detached bodies (loose cartilages), are frequently to be found in the interior of the articulation.

The *deformities of the knee*, and the treatment they require, are discussed in the essay on ORTHOPÆDIC SURGERY.

Inflammation or dropsical distension of various bursæ in the neighborhood of the knee-joint may often be met with. Besides the superficial bursa over the patella, which gives rise in its diseased condition to "housemaid's knee," there is a deep-seated bursa between the ligamentum patellæ and the tibia, which may also be inflamed, producing pain on motion, with ill-defined enlargement in the region of the anterior tuberosity of the tibia. Occasionally that part of the synovial membrane which extends upwards beneath the extensor muscles is replaced by a bursa, which may be quite distinct from the knee-joint; or an imperfect division of the membrane into two cavities may exist. When a separate bursa is present, it may be inflamed and give rise to painful swelling, which is confined, however, to the region above the patella, the articulation below remaining unaffected: this diagnostic mark is most evident when the patient is in the erect position. A swelling is often met with, especially in children, at the inner side of the popliteal space, connected with the bursa placed beneath the inner head of the gastrocnemius. As this latter bursa frequently communicates with the synovial membrane of the joint, inflammation of it is a matter of some importance, and care must be taken in our surgical treatment. Inflammation may also take place in the bursæ in connection with the *patte d'oie* tendons at the inner side of the head of the tibia, leading occasionally to most obstinate and prolonged suppuration, and interfering with the movements of the joint, which does not, however, *directly* suffer.

Woch., Aug. 6, 1877, p. 461: Ibid., Aug. 13; Ibid., p. 513; Osteitis of Knee, Berry, New York Med. Record, Jan. 31, 1880; Intermittent Hydrops Artic., Seeligmüller, Deutsche Med. Woch., 1880, No. 5. Excision of the knee-joint belongs to another portion of this work. See also Fagan, Dublin Journ. Med. Sc., Nov., 1877; Treves, Brit. Med. Journ., 1877, p. 133; Fenwick, New York Med. Record, Jan. 26, 1878.]

It may be remarked, that in *wounds of the knee-joint*, when suppuration occurs, it may take place insidiously, in the areolar tissue between the thigh-bone and the muscles which surround it, rather than in the articulation itself. In this way the whole thigh may be inflamed and swollen, and the appearances somewhat closely resemble those of acute periostitis of the femur. The depth at which the matter is situated prevents it from coming rapidly to the surface, and does not readily allow of fluctuation being detected. Much constitutional disturbance is, consequently, usually present, and the amount of pus which forms before an outlet is obtained is often very large. In such cases early and deep incisions are obviously called for; incisions which shall extend through the whole muscular layers, if the seat of the suppuration is to be reached, and the symptoms produced by the pent-up matter abated.

Diseases of the Ankle.

The ankle-joint is liable to the various diseases which have been already described, and is often involved in the progress of caries affecting the irregular bones of the tarsus; occasionally, indeed, it is not easy to decide whether the disease actually affects the ankle, or is confined to the astragalus or calcaneum; the point may, however, be determined by the free motion in the latter case of the ankle-joint when the patient is placed under chloroform. When the joint is distended with fluid, the tumefaction and fluctuation are most evident between the two malleoli, on either side of the extensor tendons; in extreme cases the effusion is perceptible also posteriorly, at the inner and outer borders of the tendo Achillis. When suppuration occurs, the matter may make its way to the surface in the immediate vicinity of the joint, or it may ascend the leg, or descend into the foot in connection with the tendinous sheaths around the ankle, so as to open at a considerable distance. The direction which the foot is prone to assume in disease interfering with the use of the joint is that of flexion, combined generally with varying amounts of inversion or eversion. The position to be selected, on the other hand, to avoid present stretching of the ligaments, and as most useful in the event of ankylosis, is that in which the foot is in the same plane with the leg, and forms with it an angle only slightly exceeding a right one. It may be remarked that disease of this joint is more favorably situated for recovery than disease of the thigh or knee, because, by the employment of a wooden leg, whilst the ankle is carefully supported by splints, exercise may be taken, and the general health consequently maintained.

Chronic osteo-arthritis seldom affects the ankle, but when it does, the tarsal joints are usually implicated at the same time. Increase in the breadth between the malleoli, which are preternaturally prominent, combined with projection inwards of the scaphoid and depression of the instep, are the appearances commonly noted.

[The subject of excision belongs properly to a different portion of this work, but it has lately been brought into prominence in discussing the treatment of joint affections.

Since the introduction of antiseptic surgery, conservative surgery, *i. e.*, the treatment without amputation or excision, has received valued reinforcement by the introduction of incisions into the joint, which in the knee-joint has been shown to be of less danger than was formerly believed to be the case.

Excision is, in the treatment of the larger joints, hip and knee, to be regarded at present as a procedure to be used when it is impossible to carry out the expectant plan, for which a long time is needed. Mr. Holmes claims that the results after excision of the hip-joint are not, as far as usefulness of the limb is concerned, as successful in its results as expectant treatment. It must be confessed, however, that much better results have in the last decade been reported after excision than were commonly attained before.[1] The advantages of conservative surgery in caries of the ankle (including the tarsus) have been urged in a paper recently presented to the Therapeutical Society of New York, based on a study of 16 cases. In 14 of these recovery took place after a period of two and a half years, and 2 died from exhaustion after suppuration. The treatment consisted of incision whenever pus came to the surface, and the removal of loose bone, but without excision.[2]]

Diseases of the other Articulations of the Foot.

The tarsal bones are so small, and the articulations between them so numerous and in such close proximity, that distinctions between the morbid conditions of the two can with difficulty be drawn. Disease in the tarsus, in the majority of

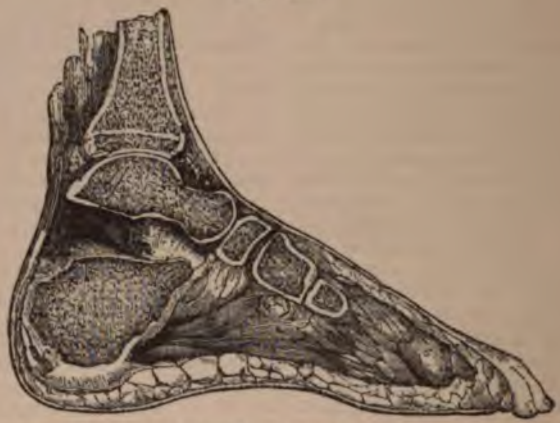
---

[[1] Brit. Med. Journal, 1880, Aug., p. 252; also Med. Times and Gazette, Nov. 3, 1872.]

[[2] New York Med. Record, Aug. 21, 1880.]

cases, arises in strumous inflammation of the bones, which soon extends to the cartilages and to the synovial membranes. Occasionally, however, an articulation is the starting-point, as may be seen represented in the accompanying illustration (taken from a preparation in the St. George's Hospital Museum), in which the disease is found commencing in the joint between the astragalus and calcaneum.

Fig. 682.



Disease of the tarsus, commencing in the joint between the os calcis and astragalus. (From a preparation in the Museum of St. George's Hospital.)

Some importance must be attached to the original seat of the mischief, in consequence of the varying degrees of simplicity of the synovial membranes; of these, the median, or *scapho-cuneiform*, is by far the most complicated, as it extends between so many tarsal bones. When disease involves only the simpler synovial membranes, or is confined to single bones in connection with them, the probabilities of a successful issue are comparatively great; and if operative measures are necessary, excision of individual bones may be had recourse to with satisfactory results. I have several times removed the calcaneum, the cuboid, or even the internal cuneiform, and recovery has occurred with a very useful foot. When disease affects the astragalus or the scaphoid, on the other hand, and the contiguous synovial membranes are implicated, the chances of localizing the mischief become much diminished; though one or both of these bones can often be removed successfully, leaving a very effective foot.[1] The middle and external cuneiform bones, also, are unfavorably situated, though less so, perhaps, than the astragalus or scaphoid. It may be remarked, that the repair which takes place after excision in these cases is usually most complete, for a large portion of the periosteum is, and ought to be, left behind in the operation; reproduction of the bone consequently occurs to a greater or less extent, giving to the foot all the solidity which is required. After removal of the whole of the calcaneum, I have found the heel perfectly rigid, and the amount of deformity very trifling.[1]

[Two cases with autopsy are reported in Gaz. des Hôpitaux, April 28, 1877. The affection is said by Gosselin to be most common in adults. There is no alteration in the position of the foot, and no deformity. The pain may be quite acute on pressure near the scaphoid. Motion of the foot is not painful, but the patient may be unable to bear any weight upon the foot.[2]]

Inflammation of the complicated *scapho-cuneiform* synovial membrane may be looked upon, according to Mr. Erichsen, as a distinct affection of the foot, commencing usually in disease of the scaphoid. At first there is pain and swelling in the region of the joint between the scaphoid and cuneiform bones. The pain is increased by bending down the foot, and extends across the tarsus to its outer side, as the articulation between the external cuneiform and the cuboid becomes involved. At a later period "the foot assumes a remarkable bulbous or clubbed appearance; the symmetry of the heel and the outline of the ankle are unimpaired, but the fore part and dorsum of the foot are greatly swollen, glazed, and possibly perforated by sinuses discharging their unhealthy pus."[1]

[1] See also Pathological Transactions, vol. xi., p. 217, for an account of the condition of the parts in a foot from which I had removed two of the tarsal bones.

[[2] Also Gaz. des Hôpitaux, Oct. 6, 1877, p. 922; Chambard, Thèse de Paris, 1877; Tarsalgia des Adolescents; Duplay, Gaz. des Hôp., Oct. 9, 1879.]

The diseases of the metatarsal and phalangeal articulations call for no special observations. They are frequently *gouty* in their character, or, in some cases, are examples of *chronic osteo-arthritis*. It is worthy of notice, perhaps, that in the metatarso-phalangeal articulation of the great toe, the deformity induced by the latter affection has been mistaken for dislocation; a condition which it may closely resemble.

The subject of *bunion* is considered in the essay on SURGICAL AFFECTIONS OF THE SKIN.

Diseases of the Sterno-clavicular, Acromio-clavicular, and Sternal Joints.

A certain amount of enlargement of the *sterno-clavicular* as well as of the *acromio-clavicular* articulations may sometimes be seen in persons who have long been in the habit of working hard with their upper extremities. Acute inflammation of the *sterno-clavicular* joint is also met with occasionally. Such a case in an adult came under my care, in which suppuration rapidly took place, with destruction of the fibro-cartilage, inducing spontaneous dislocation of the inner extremity of the clavicle. The shoulder and arm having been fixed, and the dislocation reduced and prevented from recurring by appropriate splints, recovery took place with a useful extremity.

Disease of this joint is easily recognized, but, owing to the great mobility and peculiar anatomical characters of the articulation, it is difficult to secure perfect rest, and, for like reasons, ankylosis is seldom met with. Cases of sterno-clavicular disease will be found related in Mr. Hilton's work on Rest, and in the Lancet of April, 1864.[2]

Chronic osteo-arthritis of these articulations may also occur, producing enlargement of the articular extremities of the clavicle, stiffness and pain on movement of the joints, as well as weakness of the upper extremity.

Disease of the *articulation between the first and second pieces of the sternum*, where no synovial membrane exists, is rare, but an interesting case is related by Mr. Hilton, in which the principal symptoms were pain about the sternum, especially on coughing or talking, or making any respiratory exertion, with difficulty of breathing, and great tenderness on direct pressure on the joint. Recovery ultimately took place.

Diseases of the Shoulder.

The shoulder-joint resembles the hip in its anatomical characters, but is, fortunately, far less subject to disease, and when disease occurs the results are usually much less severe, the persistence of pain and the production of rigidity constituting the conditions most to be apprehended. If suppuration takes place, which is seldom the case, the matter often follows the course of the long tendon of the biceps, and opens at the front of the arm below the deltoid. Not unfrequently, too, it passes out of the articulation by the opening which exists in the synovial membrane beneath the subscapularis, and follows that muscle, arriving at the surface near the back and lower part of the shoulder. The most favorable position in which a diseased shoulder can be placed for treatment, is that which is almost naturally adopted; the arm should be parallel to the trunk, and the elbow slightly separated from the chest, the forearm being at the same time supported by appropriate mechanical means. If ankylosis takes place, owing to the great mobility of the scapula, the arm may still be moved very freely, and the limb consequently remains very useful.

The condition of parts induced by *chronic osteo-arthritis* of the shoulder has, no doubt, been frequently mistaken for the result of injury. After the stage of synovial distension has passed, wasting of the soft parts occurs; rigidity, as well as crepitation on movement, are met with, and the head of the humerus appears to be elevated and carried forwards. When the disease is of long standing, the deltoid is atrophied. The capsular ligament is usually thickened, and has sometimes osseous particles in its substance, or it may be perforated at its upper part. The synovial membrane shows marked signs of inflammation. The glenoid fossa loses its ligament as well as its cartilage, and presents the characteristic ivory-like material; occasionally, too, irregular osseous growths are found around its edges, increasing its capacity. The under surface of the acromion, and even of the acromial end of the clavicle, may be hollowed out by pressure of the humerus upon them, and are often covered with a polished porcelain-like material. Separation of the acromion into two portions is also met with sometimes. The head of the humerus is often much enlarged, and its surface eburnated. The tendinous structures around the joint may appear partially disintegrated, and the intra-articular part of the long head of the biceps is usually destroyed, the remains of the tendon adhering to the edges of the bicipital groove.

[[2] Lancet, 1876, vol. ii., p. 748; Centralblatt f. Chirurgie, No. 10, 1877]

Disease of the *deep-seated bursæ* around the shoulder-joint is occasionally met with, and may prove somewhat perplexing. The bursæ beneath the *subscapularis* and the *infra-spinatus* habitually communicate with the synovial membrane, so that their diseases are in fact those of the articulation itself. The bursa beneath the *deltoid* is distinct; and when that bursa is inflamed, the muscle is rendered unusually convex, and any contraction of it is attended with pain. The articular surfaces, however, can be freely pressed together, and the joint exercised without suffering, provided the deltoid is not used, and no pressure is made on the tumor. A sensation of fine crepitation can often be felt in these cases on moving the shoulder.

[Duplay has described as periarthritis of the shoulder-joint the condition of stiffness or limited motion which is not infrequently seen following comparatively slight injuries. A certain amount of pain accompanies motion beyond a certain extent, although some motion is possible by reason of the mobility of the scapula. Atrophy of the muscles is present, and at times some spontaneous pain. The arm becomes useless, and the affection does not improve without treatment. Forcible motion breaks down adhesions and usually effects a complete cure, but sometimes two or three attempts are necessary before complete recovery.[1]]

Diseases of the Elbow-joint.

The diseases of the elbow resemble those of the knee, although they are less severe in their character, and more favorable in their results. This remark, indeed, applies, for obvious reasons, to all the articulations of the *upper* as compared with those of the *lower* extremities. When effusion takes place into the synovial membrane of the elbow, the swelling is most evident at the back of the arm, on each side of and above the olecranon; it is also perceptible at the outer side of the forearm, beneath the extensors. If suppuration occurs in the joint, the direction in which the matter can make its way with the greatest ease is upwards and backwards between the humerus and triceps; abscesses point, therefore, usually at the borders of this muscle, the outer being the border more commonly selected. The synovial capsule may also give way in front, in which case sinuses will be met with at the side of the brachialis anticus. If the bones are diseased, however, the fistulous orifices may lead directly to the part which has become necrosed or carious. In cases of *strumous osteitis*, which is somewhat common in this region, complete death and separation of a portion of bone in the olecranon, or in one of the condyles, frequently *with* but sometimes *without* the existence of caries, is by no means unusual. A comparatively slight operation, therefore, is occasionally successful in cases where excision of the articulation might at first sight have appeared necessary. The radius, it may be remarked, is less prone to suffer than either the humerus or the ulna.

The position in which the joint should be placed when splints are required, is that in which the forearm forms a right angle with the arm, and is in a state intermediate between pronation and supination. As the joint naturally falls into this position in consequence of its affording the patient the greatest amount of relief, secondary dislocation is rare, the only one which is met with being luxation of the head of the radius outwards and backwards, depending probably on the hand having been kept in a state of forced pronation.

Chronic osteo-arthritis, when it attacks the elbow, is seldom confined to a single articulation, so that the nature of the affection is usually clear. Bony nodules and vegetations are of frequent occurrence in this disease, taking the form occasionally in the ulna of "additamentary bones." Detached or pendulous bodies are often met with, sometimes in great numbers.

Disease of the bursa over the olecranon, constituting "miner's elbow," can scarcely be confounded with disease of the joint. When inflammation attacks the bursa beneath the triceps, however, more care is necessary. According to Mr. Barwell, the condition here closely resembles that which is met with in the knee; a synovial bag existing between the triceps and the humerus, which may be a distinct bursa, or, as is more commonly the case, be a prolongation of the articular synovial membrane. Mr. Barwell remarks that, in inflammation of the bursa when it does *not* communicate with the joint, "there will be no swelling or puffiness between the inner condyle and olecranon process when the arm is bent at right

---

angles; but the infallible test is, that the line of junction between the head of the radius and the humerus is as clear and well-defined as ever. If, on the other hand, the inflamed structure communicate with the joint, then these parts will participate in the general puffiness and swelling.[1]

Diseases of the Wrist, and other Articulations of the Hand.

The complicated relations of the various synovial membranes at the wrist and around the carpal bones facilitate extension of disease from one to the other; the anatomical arrangement explains also, to a certain extent, why it is that the bones are so frequently affected in articular disease of this region. The most favorable position in which the hand can be placed in disease of the wrist is one intermediate between flexion and extension, as well as between pronation and supination. This position is the one naturally adopted when the hand and arm are supported in a sling. In the recumbent posture, however, the hand usually lies on a cushion in a state of complete pronation: a condition which places the posterior ligaments on the stretch, and favors luxation backwards, the only form of spontaneous dislocation to be apprehended. In acute inflammation of the wrist, therefore, relief may often be afforded by so adapting the mechanical support as to obviate this tendency to pronation. If luxation of the ulna has already occurred, and the triangular fibro-cartilage been destroyed, the hand must be secured in the position recommended, and pressure exercised on the back of the ulna to reduce its dislocation, and maintain the bone in its normal position. As stiffness of the fingers is very apt to occur from want of exercise in cases of diseased wrist, passive motion of their articulations must be had recourse to as early as possible.

Chronic osteo-arthritis of the wrist is most common in females beyond the middle period of life, though it is met with occasionally at an early age in both sexes. The back of the wrist in this form of disease exhibits usually a peculiar projection in consequence of enlargement and partial luxation backwards of the ulna, and, though to a much less degree, of the radius. The fingers are frequently distorted, becoming permanently flexed as well as adducted; the *second* phalanges, however, of the fingers, as well as of the thumb, are usually *extended*, giving to the hand a peculiar appearance highly characteristic of the disease in its advanced stage. Enlargement of the articular extremities of the fingers is very common, representing the "nodosities" of Dr. Haygarth. Partial or complete luxations of them may also be present.

Synovial tumors, or "ganglia," about the wrist are treated of in the essay on AFFECTIONS OF THE MUSCULAR SYSTEM.

Diseases of the Temporo-maxillary Articulation.

The only affection of this joint to which it is necessary specially to direct attention is *chronic osteo-arthritis.* This disease usually attacks the jaw in old persons, though it has been seen in early life; generally speaking, too, it is constitutional rather than local, and shows a marked disposition to symmetrical disturbance. The condyle and ramus of the lower jaw are usually enlarged and elongated; in a case related by Cruveilhier, however, the condyle was found to be entirely absent. The glenoid cavity is more or less altered, being frequently enlarged, and sometimes forming a plane surface. The articular cartilage and fibro-cartilage generally disappear, but the porcelain deposit is not common, and foreign bodies are rarely, if ever, present. The symptoms consist principally in stiffness of the jaw, and inability completely to open the mouth, with a crackling noise when the joint is used. The face is distorted; if only one articulation is affected, there will be some projection, and the face is turned towards the opposite side. When both articulations are diseased, the whole jaw is carried forwards. The symptoms are commonly less urgent than those presented by the same disease in other joints, but Dr. Humphry refers to a case in which this disease caused so much discomfort and distortion of the face, that he was led to excise the condyle of the affected joint, and with very good result.[1] A case, too, is related by Mr. Hilton, in which osseous ankylosis of this articulation had occurred to a considerable extent on both sides, in a man in whom ankylosis was also found between the skull and atlas, as well as between some of the succeeding cervical vertebræ.[2]

DISEASES OF THE SPINE.

By Alex. Shaw, Esq.

Revised by E. H. Bradford, M.D.

The spine is subject to a disease, commencing in its bones and joints, so formidable in its results, that it is emphatically called Disease of the Spine. From Caries being the kind of morbid action which invades the bony structures, that term is sometimes used to designate the disease. Owing to an angular projection or hump being formed in the spine at the chief seat of the disease, and to distinguish it from Lateral Curvature, the name Angular Deformity is sometimes applied. The term Malady of Pott, derived from the first standard description of the disease having been given by our countryman, is still occasionally met with, but only in foreign works.

Disease of the spine is correctly included among those of the joints generally. The morbid action which leads to the destruction of parts of the bodies of the vertebræ and fibro-cartilages, is identical with what attacks other articulations. But as the spine combines several offices essentially distinct from each other, such as being a flexible column and at the same time the guardian of the spinal cord, its diseases present special characters, which justify their being treated of separately.

[The pathology of bone has recently been the subject of careful investigation, and particularly the morbid processes to be found in suppurative joint affections, and the kindred disease caries of the spine. Köster and others have demonstrated that miliary tubercles are almost invariably to be found in fungous arthritis, and conclude that the process must be regarded as essentially a tuberculous one. Feurer[1] has recently examined, with reference to this point, 12 specimens of caries of the spine; in nine of these miliary tubercles were found in the diseased tissue, with suppuration in four; tubercles were to be found in other organs also. In the remaining 3 specimens, no tubercles were found in the bony tissue. In 1 of these, however, miliary tubercles were found in the pericardium, but not elsewhere; in this case suppuration was present, but it was absent in the other two.

As elsewhere in similar affections, the first known pathological change consists of increased vascularization; widening of Howship's lacunæ; inflammatory changes in the marrow follow, the normal fatty tissue is replaced by granulation-cells which may undergo fatty degeneration; the lacunæ become enlarged, are filled with cellular tissue, and the bony substance is absorbed or necrosed. It is as yet undetermined whether the vascularization of the bone-tissue is the result of an increased flow of blood in the canaliculi, or to the extension of new vessels from the marrow. Authorities differ also as to the part played by the osseous substance in this process of inflammation, whether the tela ossea is simply inert and is absorbed, or whether the bone-corpuscles primarily undergo degenerative changes.[1]]

Caries: ulceration.—The disease called caries is generally considered to be a morbid process confined to bone. The part of the bone attacked, commonly circumscribed within a small area, at first, is gradually consumed by disintegration and absorption. The fibro-cartilages contiguous to the diseased bone undergo what appears a similar and simultaneous destruction of substance. And during the process, there is a constant discharge of pus, both from the bone and the cartilages. Hence it may be concluded that the diseased action in bone called caries, is the same that, witnessed in the fibro-cartilages, is called ulceration.

The question has been mooted as to whether the morbid process commences in the osseous or fibro-cartilaginous structures. It seems enough to know that when the disease has proceeded for a short time, all the textures yield indiscriminately to its destructive agency. In childhood, temporary cartilage enters into the composition; yet we find that bony, fibrous, fibro-cartilaginous and simply cartilaginous tissues are all disintegrated and removed in an apparently identical manner.

[Simple as the diagnosis of caries of the spine is when a marked projection of the spinous processes can be determined, in the earliest stages the disease is not always so readily recognized.

---

[1] Virchow's Archiv, 1880, p. 89.]

[1] Cadeillan, Paris, 1880. De l'osteo-myelite aigue des corps vertebraux, cause du mal de Pott.]

Stiffness of the back at the affected portion is very characteristic, and is due to muscular contraction similar to that seen about affected joints. In cervical caries this frequently gives rise to torticollis, and in dorsal disease, in some instances, a spurious lateral curvature may for a while mask the incipient Pott's disease. When the lower dorsal or lumbar region is affected pronounced lordosis is often to be seen, and in caries in a higher part of the spine the patient will sometimes throw the head back to prevent its weight from bending the spine forward and crowding the diseased bodies together.

The phenomena (strictly nervous in character) vary according to the location of the disease. When the upper dorsal and cervical region is involved, a "grunting" respiration and cough and attacks of severe dyspnœa may take place. Patients with incipient caries of the spine have frequently been treated as asthmatic or suffering from bronchitis.

In a similar way, disturbance of digestion, "dyspepsia," with occasional attacks of vomiting, severe abdominal pain, "gastralgia," vesical irritation with severe pain in the testicles and penis, follow disease of the corresponding portion of the spinal column. The most notable example of this was furnished by a patient who underwent the operation of lithotomy for symptoms which on autopsy were found to be due simply to caries of the spine in the lumbar region.[1]]

Anterior segment, the special seat of the disease.—An important distinction exists as to the segment of the spine to which the morbid action confines its attacks. It is a remarkable pathological fact, that spinal disease selects the bodies of the vertebræ, the fibro-cartilages, and the accessory ligaments, forming the anterior segment of the spine, as the particular objects of its invasion; to the exclusion of the pedicles, arches, transverse, oblique, and spinous processes, together with the ligaments and articulations, which form the posterior segment. That is, caries and ulceration commence in the anterior portion of the column, destroy it extensively from front to rear, and proceed both upward and downward; but they do not go backward, or cross the line of partition between it and the posterior portion. It may be deemed singular that, numerous as are the small joints formed by the opposing surfaces of the oblique processes, in the posterior segment, disease is scarcely ever witnessed in them. It will presently be seen that the structures of that segment have a remarkable disposition to take on reparative action, in antagonism, as it were, to the morbid action in front.

Disease of the spine occurs with equal frequency in the two sexes. It may commence at any period of life; but it is extremely rare past the middle term; it is most rife from early childhood to adolescence.

The disease is generally admitted to be one of the class called scrofulous; yet it is often met with in persons who do not otherwise show signs of that diathesis. Its origin is frequently attributed by the patient or friends to an accident, as a fall, that probably occurred a long time previously. But the evidence of the connection is seldom satisfactory. Greater importance is due to the unsound constitution which would cause such disproportionate effects to proceed from a slight injury.

Incipient stage of disease of the spine.[1]—The symptom which commonly attracts the notice of the friends of the patient first, and which is also the most important in the mind of the surgeon, is a prominence of one, two, or more spinous processes at some part of the column.

Unprofessional persons will speak of that projection as a "growing out" of the back. To the surgeon it is significant of a certain portion of the front of the spine having been destroyed by disease. He infers that an excavation there has caused the superior part to fall down at an angle to the inferior; and concludes that as the bend is directly forward, the loss of substance must be in the bodies of the vertebræ and intervertebral cartilages. The apex of the angle, it will likewise be perceived, will be formed by the spinous process of the vertebra in which the destruction has been greatest.

In the advanced stage of the disease, no symptom can be more easily detected than the prominence of the spinous processes; for the muscles in each trough will have become atrophied from want of use; and the ridge will stand out conspicuously like a keel, with rugged, serrated edge, each knob distinct; the transverse and oblique processes may even be well-marked. But in the recent stage, when the angle has just begun to appear, there are sources of obscurity, which sometimes make the diagnosis difficult. The protuberance can be more easily discerned in some of the regions of the spine than in others. It can be recognized in the dorsal before it can in the lumbar; and

---

[[1] New York Med. Record, April 24, 1875.]

[[1] Sur la polyarthritis vertebrale; Broca, Gaz. Méd. de Par., 1879, pp. 454, 465.]

the reason is obvious. The natural curve in the dorsal region, has its convexity presenting backward; the ridge of spinous processes is, therefore, comparatively superficial; hence a trifling increase of the natural bend, caused by the destruction of even a small part of one of the bodies, will be distinctly apparent. But it is different in the lumbar region; the natural curve there has its convexity presenting forward, and owing to the hollow in the back, the tips of the spinous processes are situated comparatively deeply. When there is loss of substance, therefore, in the front or convex aspect of the curve, consequent on carious ulceration of the bodies and intervertebral cartilages, it may be long before the spine will fall forward, and bend in the reverse direction, so that the ridge of spinous processes shall form a convexity and visible projection posteriorly. Moreover, from the great depth and magnitude of the lumbar vertebræ, it is obvious that the destruction of their substance must be proportionally extensive, for the column to be bent at an angle. In the cervical region, the normal curve is similar in direction to that in the lumbar. When the disease, however, attacks the vertebræ there, the effects differ from what are observed elsewhere; the portion of spine above the carious ulceration does not fall forward; the weight of the head overcomes that tendency; and the result is that the head subsides vertically, so as to approximate to the upper part of the chest, and obliterate the appearance of the neck. Accordingly, the occiput comes in the way of an examination, preventing the tips of the spinous processes from being felt by the fingers.

But in reference to these normal curves of the spine, it is to be remembered that they are not properly established till about puberty; and that up to that age, the column is very flexible. A difficulty of diagnosis is, therefore, sometimes found in young patients, as a consequence of this suppleness; especially if they have been previously debilitated by illness. When a weakly child sits, he usually stoops; and if the spine be examined, the ridge of spinous processes will probably project conspicuously and alarm the parents; it is not unlikely, moreover, that the chief protuberance will be about the middle of the lumbar region, where a hollow might be expected in the adult. If it should be apprehended that disease of the spine was commencing, the point of greatest interest would be to observe whether there were any distinctly abrupt projection of one particular spinous process, to mark it as the apex of an angle, however obtuse. Should doubt still remain, the child may be laid on its belly, and the hips elevated to a higher level than the spine; if the structures be sound all appearance of the abnormal protuberance will then be removed; if, on the contrary, the projection be consequent on disease, it will continue to be perceived.

Rigidity of the affected portion.—For the detection of disease in the spine at an early period, no symptom is more valuable than diminution of the natural flexibility of the column at the suspected part. And the reason why that defect should indicate disease at its incipient stage, may be stated. Pathology teaches that as soon as caries and ulceration attack the bodies of the vertebræ and intervertebral substances, adhesive inflammation is set up in the adjoining structures, more particularly in the posterior segment of the spine. Coagulable lymph is thrown out in the interstices of the laminæ, joints, and processes situated at the back; and as the lymph solidifies the vertebræ become agglutinated and deprived of their natural mobility. Parallel instances are met with in diseases of the joints elsewhere: for example, an early symptom in hip-disease is interruption of the free motion of the articulation. The rigidity of the spine may be made evident by the simple expedient of directing the patient to stoop forward, and rise alternately; or to incline his body first to one and then to the other side; if the column be carefully watched during these movements, and caries has commenced, a distinct contrast will be perceived between the natural flexibility of the spine throughout its principal extent, and an abnormal inflexibility in the portion occupied by about four or five adjoining vertebræ. The latter bones will appear to be moved as a united, compact mass. Or if the palm of the hand be planted broadly and flatly over the vertebræ suspected to be diseased, including some of the sound adjoining parts, and if the patient be asked to stoop and rise as before, a distinct sense of movement among the various processes will be communicated to the fingers at the sound part, while there will be an absence of such a feeling at the diseased part.[1]

Heat and swelling.—When the disease is acute and the ulceration in active progress, both these symptoms will be present. The increase of temperature may be ascertained by the touch, but it will be certified better by the thermometer. The swelling is seldom such as to be prominent and distinct; it consists rather in a general fulness which partially obscures the forms of the bones. When considerable, it indicates an actively progressing condition of the caries. When absent, and the points and surfaces of the bones are visible and defined, it furnishes an argument for supposing that the disease is dormant and that ankylosis may have taken place.

---

[1] [Physiological curves of the vertebral column; Balandin, Virchow's Archiv, June 10, 1873.]

Pain.—This, which is a faithful guardian in general of the textures of the frame, is a fallacious monitor in regard to disease of the spine. It fails to warn when danger is imminent, and it alarms needlessly. As a proof that carious ulceration of the vertebræ is not always attended with pain, it may be stated that numerous patients have gone through the whole course of the disease, so as to have angular deformity of the worst description, without having been confined to bed a week or day, from inability to go about. Again, other patients, almost always females, have suffered sharp pain in a part of the spine, from supposed disease, while every vertebra was perfectly sound. Nevertheless, in acute cases of real disease of the spine, pain in the affected part of the back is a leading symptom. It will be varied sometimes by the feeling of painful constriction about the epigastrium, as if a cord were tied round the waist. The act of raising the patient, or turning him round in bed, will cause great agony. If his limbs be affected with convulsive startings the shock communicated to the spine will be attended with much pain. His nights will be sleepless. Such attacks do not commonly last long, but they are apt to recur; they indicate accessions of the acute morbid action.

In a large proportion of cases, pain is a subordinate symptom; and some devices are necessary to make it be felt. While the patient is upright, a shock may be given to the spine, by placing the hands on both his shoulders, and suddenly depressing them; the jerk will probably cause pain in the affected part. Or he may be asked to jump from a low stool upon the floor. Percussing each spinous process in succession is another mode. The plan of carrying a hot sponge down the spine, in the expectation of the warmth bringing out the pain, has not much to recommend it. When dull aching pain, always returning to the same part of the spine, follows exercise, jolting in a carriage, or sitting for a long time, it betokens latent disease.

Neuralgia of the spine.—It is necessary, for assisting diagnosis, to notice here a kind of pain which fixes itself in some particular spot of the spine, and is liable to be mistaken for a symptom of organic lesion. It differs from those pains in the back which can be traced directly to rheumatism, dyspepsia, diseases of the kidneys, or of the uterus, or ovaries. The affection is nervous and functional. It may be considered to have the same relation to the spine which clavus hystericus has to the head. Pains resembling it visit different parts of the body; but they have one common character in affecting females prone to hysteria almost exclusively. Sir B. C. Brodie gave to them the name "hysterical neuralgia." They are not uncommon in the joints generally, particularly the knee. When that articulation is affected, the pain may be of long duration, exhausting to the constitution. It has fallen to the lot of the writer to have witnessed two cases of that hysterical neuralgia of the knee-joint, in both of which the patients, young females, consented to lose their limbs on account of the severity of the pain. They were under the care of the same surgeon, who conceived that their sufferings were owing to acute ulceration of the cartilages of the joints, requiring amputation; and chloroform had not then been introduced. In both cases, the cartilages and all the other structures of the joints were found, after the operation, to be perfectly healthy. The lesson taught by these examples, and enforced by other considerations, is that, when the spine is affected with similar pains, they may be acute and long persistent, without boding actual disease.[1]

---

[1] The subsequent history of one of these patients was not a little remarkable. Although the stump was apparently sound, it soon became the seat of pain, equal to what had been felt in the knee. Thereupon the surgeon repeated the amputation higher up. Healthy cicatrization took place; but ere long pain, as bad as at first, returned in the new stump. The next proceeding was to excise a large portion of the sacro-sciatic nerve. But this operation had no better result than the preceding. Neither surgeon nor patient, however, lost heart. As there still remained a portion of limb capable of removal, amputation at the hip-joint was performed. The large wound healed favorably. Yet the pain did not depart; it continued in the cicatrix as great as ever, and of the same kind as at first. The young woman was eventually sent to the sea-side. There she became pregnant. Upon her return it was ascertained that as soon as she felt herself in the family-way, the neuralgia ceased. Having subsequently become the mother of a large family, she has been frequently seen on account of her children; and, according to her statement, she has still occasional attacks of the old pain in the stump.

The writer has been informed of a similar case which occurred recently. The surgeon was induced, chiefly by the solicitations of the patient, a woman of hysterical temperament, to amputate her limb for supposed ulceration of the cartilages of the knee-joint. The structures were found healthy.

Every part of the spinal column would seem equally prone to be affected with this neuralgia. Perhaps it may be met with more frequently at the site of the "vertebra prominens," than elsewhere; and when seated there, the protuberance of the spinous process increases the fear that disease may be its origin. A peculiar feature of the pain is that it is circumscribed within a small area, so that the part might be covered with the point of the finger; and the description often given is that it resembles what might be produced by a nail being driven into the side of the spine. The actual suffering to which the pain gives rise is undoubtedly great; but the effect on the patient's mind is not the least of the evil consequences. She becomes the victim of unfounded apprehensions as to the nature of her complaint—being commonly possessed with a conviction that a frightful corroding ulcer, of some kind, is destroying her spine. Forthwith she is furnished with an invalid bed; and months or years may elapse before she rises from it.

The main points which deserve attention, in forming a diagnosis, are: 1, that no appreciable angular deformity exists; 2, that there is no perceptible rigidity in the affected part; 3, that while undergoing the examination, the patient will wince and jerk the body, each time the spine is touched; which is contrary to what she would do if the pain depended on disease; lastly, in reference to those cases in which the pain in the back has lasted over many months, and the lady has been confined all the while to her couch, and yet no deformity is apparent—which is the history of almost all these neuralgic cases—it may be argued that, if caries had been engaged, all the while the pain was felt, in destroying the vertebræ, deformity of an unmistakable kind would have been produced.

It is not uncommon for hysterical patients, especially those who have been long confined to the recumbent position, to lose control over their lower extremities, to have "hysterical paraplegia." When neuralgia of the spine is added, the complication no doubt increases the difficulty of diagnosis. It will, however, be perceived further on, that when paraplegia occurs as the result of carious ulceration, it is preceded by strikingly marked angular deformity of the column; a condition that does not belong to neuralgia. Yet, in certain rare cases, deformity may not be wanting to increase the perplexity.[1]

The writer had under his charge a governess, twenty-two years of age, affected with paraplegia; she suffered at the same time from neuralgia in the spine. On examining the seat of the pain, which was in the lumbar region, a projection of some of the vertebræ was distinctly visible. The patient had been obliged to relinquish her situation in a family, as it had been stated by the medical attendant that she had spinal disease, accompanied with affection of the spinal cord. From inquiry, however, into the history of the deformity, and examination of the whole spine, it was made out satisfactorily that the bulging of the spine at the loins was a consequence merely of lateral distortion; that the pain situated there was nervous; and that the dragging of the limbs and inability to walk were symptoms of hysterical paraplegia. Under treatment by physical exercises, shampooing, shower-baths, tonics, etc., she perfectly recovered in a few weeks.[1]

Angular Deformity.

When the substance of one or more bodies of the vertebræ has been removed by caries, it may easily be understood that, from the superimposed portion having been undermined, it will fall forward and form an angle with that below. The pressure of the superincumbent weight, however, is not the only agent in producing the bend; when a patient is confined strictly to the recumbent position, the angle continues to become more acute, which shows that the action of the abdominal muscles shares in causing the deformity.

Fig. 683, copied from a photograph, shows the appearances commonly presented in a case of angular deformity from spinal disease. The patient, a delicate girl, fourteen years of age, had become deformed to the extent seen in the drawing, shortly before her admission into the hospital. She had been generally able to go about and attend school during the progress of the deformity. Latterly, she failed in her power of walking. But it was ascertained by frequent observation that this defect did not proceed from paraplegia, but only from inability to balance herself in the newly-deformed

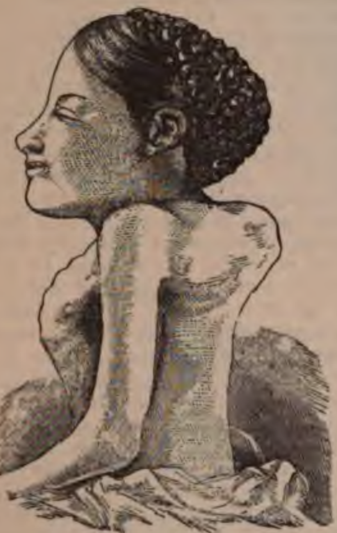
condition of the upper region of her body. She became strong on her limbs after a short stay in the hospital.

Fig. 683.



From the bodies and fibro-cartilages in which the loss of substance takes place, being in the median line, the descent of the upper portion is generally in a direction straight forward. That, at least, is invariably the case in the dorsal region. But in the dorso-lumbar and lumbar regions, at which greater latitude of motion exists, a lateral deviation will sometimes be combined with the movement forward. The surgeon may be deceived by that inclination to one side; and commit the dangerous error of supposing a case of angular deformity to be one of lateral distortion.

The writer was consulted about a girl, aged fifteen, who had a projection at the dorso-lumbar region, with a distinctly marked deviation of the spine to one side, simulating closely lateral curvature. The medical attendant had considered the case to be of that kind, and put the patient on a course of calisthenic exercise. It was distinctly ascertained, however, that the prominence was the effect of caries; and the principal diagnostic sign was the directness with which the spinous processes stood out backwardly, against the skin; for it is a never-failing observation in regard to lateral distortion, that, owing to the rotation of the column on its long axis, which always accompanies incurvation, the spinous processes are pointed laterally toward the concavity, and that to such a degree that they are nearly hidden from view by the overlapping of the edge of the longissimus dorsi.

But angular deformity does not consist merely in a falling forward of the undermined portion of the spine, while the inferior remains erect. It is not the same as when a rigid pole, like a flagstaff, is broken by the wind, and the upper part falls over. Were that the case, a patient in whom the spine had become bent would not be able to preserve his equilibrium; his head would be thrown inordinately in front of the line of gravity, and if he attempted to walk, he would be precipitated forward. When a person, therefore, has spinal disease, yet is able to be upon his legs, he is instinctively led to make certain efforts for restoring the balance; the nature of which the accompanying diagram is intended to illustrate. In his first endeavors, he grasps both thighs above the knees with his hands, thus making supports of his arms; he tries at the same time both to elevate the head, and to carry the upper part of the body back, obviously with the design of bringing them more directly into the centre of gravity. Eventually he succeeds; and it is obviously by causing the portions of the column above and below the angle to arch backward. But these incurvations will have the effect of carrying the angle itself also backward. Hence

Fig. 684.

the prominent "hump," which is such conspicuous feature in the deformity from spinal disease, is produced. It may also be perceived that the apparently proud air with which the patient carries himself—his face turned upward and his body thrown back—is merely an effect of his continued efforts to restore the head to its proper vertical position above the base of the spine. When the disease is in the lumbar vertebræ, and a deep chasm is formed just at the base, the column falls down in its whole length; there are therefore no means of transporting the angle backward in the manner described above; and the patient is in the pitiable condition of being obliged to carry his body horizontally, *ventre a terre*, progressing on his knees, or feet, and hands.[1]

Changes in chest and abdomen.—When the disease is seated in the dorsal region the whole thorax is included in the deformity, and the abdomen partially; the trunk being at the same time diminished in height, as well as rendered broad and square, without distinction of waist. Owing to the falling forward of the portion of spine above the diseased part, the antero-posterior diameter of the chest is increased in length; the sternum also protrudes, being sometimes bent at an obtuse angle; and the projection there forms a kind of counterpoise to the posterior protuberance. The viscera both of the thorax and abdomen accommodate themselves, by alterations in their forms, to the changed condition of the walls of their respective cavities, neither their internal structure nor their functions appearing to suffer. The œsophagus and trachea are simply shortened; the aorta, having to give off its intercostal branches, follows the course of the spine, and is, therefore, about its natural length.

The disease sometimes attacks two different parts of the column, either at once, or at distinct periods; thereby causing two angular projections of the spine in the same patient. In the last case witnessed by the writer, the boy had just recovered from disease in the dorso-lumbar region, when it appeared in the cervico-dorsal vertebræ; there it extended to the spinal cord, and the patient died in a few months with paraplegia.

Spinal Abscess.

The importance of the subject of abscesses connected with disease of the spine, may be judged of when it is stated that they are the most frequent causes of death in this complaint. Yet happily in a large number of cases the disease runs its whole course, producing extreme deformity and ending in ankylosis, without evidence of any abscess having formed.

It has been shown above that the destructive effects of spinal disease are confined to the anterior segment of the column; and that while the morbid processes are committing extensive ravages there, an opposite reparative or defensive action is going on in the posterior segment. Now, the different courses followed by spinal abscesses cannot be properly understood unless the influence of these distinct agencies be kept in view.

And here a remark concerning the constitution of abscesses generally may not be out of place. It belongs to all abscesses to have an element of self-cure as well as of increase. In the walls of a simple abscess two different processes are observed to be going on. The deeply-seated part of the parietes carries on a formative action, opposed in its nature to an absorptive one in the more superficial part. And it is by the concurrent growth at the bottom or basis, and removal and thinning of the structures toward the point of acumination, that the contents are eventually brought to the surface and discharged. On the pus being evacuated the cavity is filled up by granulations springing from the under surface, on the same principle as a wound is healed by the second intention. When the abscess is cured by resolution, it is from the adhesive, formative, or reparative process overcoming the suppurative and absorptive. The pus is then taken up and carried into the system; the walls proportionately thicken by new growth till they close in and obliterate the cavity.

The mode in which an abscess is first formed, in disease of the spine, appears to be as follows: The morbid process being a species of ulceration, the act of removal of substance is accompanied with suppuration. In an ordinary ulcer, say of the skin or mucous membrane, the pus thus discharged is either collected under the dressings or washed away. But in the spine the matter is caught by the connecting tissue; that becomes thickened and condensed; and at length an abscess, with proper pyogenic membrane, is constructed. When a collection of pus is thus formed, various causes may lead to its progressive increase. From the denudation of the bone and fibro-cartilages, and the exposure of their surfaces to the pus, the ulceration may be expected to spread. Owing to the natural flexibility of the spine the attrition between the opposing diseased surfaces will be great; but it will be made worse by the additional mobility consequent on the destruction of the fibro-cartilages and other ligaments which con-

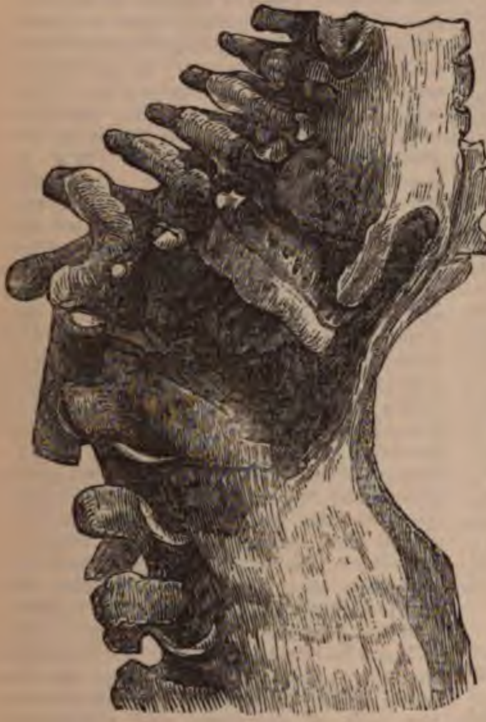
---

[1 Disease of spine without angular deformity, Br. Med. Journ., April 24, 1880, p. 627.]

nect the vertebræ. Again, in proportion as the excavation proceeds, and the spine becomes more bent, all the adjacent structures in front of the column will become further relaxed, and so facilitate the accumulation of pus in the abscess.

The patient from whom the specimen represented in fig. 685 was removed, was a blacksmith, twenty-eight years of age, and was admitted into the hospital for a psoas abscess, about the size of a large orange, situated in the left groin. He had an abrupt angular deformity in the back, with protuberance of the sternum; and his muscles, particularly those of the upper extremities, were largely developed. The deformity had taken place when he was fourteen years of age; and it had not increased since. His father being a blacksmith, he had been early put to the same work, and had continued uninterruptedly at it till three weeks before his admission, when he first noticed the swelling in the groin. On the abscess being tapped, a straw-colored fluid was discharged; the opening did not heal; ordinary pus continued to flow; and he died exhausted with hectic fever. It will be remarked in the figure that the posterior arches and articular processes of the vertebræ, at the seat of disease, have been firmly united together by bone.

Fig. 685.



Yet experience shows, as already remarked, that in a large number of cases the disease proceeds to the effect of producing extreme deformity, even combined with paraplegia, without any signs of abscess presenting themselves. But it is not to be concluded on that account that abscess has not existed in these cases. Owing to the inaccessible situation of the diseased parts, a collection of matter may have formed in connection with the carious vertebræ, and its presence would not be known if it remained of small size. An abscess, therefore, arrested in its progress before becoming sufficiently large to show itself outwardly, might have been lodged for an indefinite length of time in the angle of the diseased bones, and been eventually removed by resolution, without its existence having been suspected.

Let it therefore be asked, under what conditions it may be expected that an abscess in course of formation, in contact with diseased vertebræ and fibro-cartilages, may be arrested in its progress and dispersed? That inquiry introduces the subject of ankylosis.

Ankylosis.—When inflammation of the adhesive type affects a bone, the first change observed is a thickening of the periosteum, extending more or less to the connecting tissue around; by that means the adjoining structures are agglutinated and a bed prepared for the deposit of ossific matter. As stated before (*supra*, p. 302), one of the consequences of caries attacking the bodies of the vertebræ is, that adhesive inflammation is set up in the posterior segments of the bones. It may therefore be assumed that shortly after the commencement of the disease, the connecting tissue in the interstices of the vertebræ behind, will be consolidated, and by taking on the office of additional ligaments, will bind the arches and different processes together. The immediate effect of this cohesion of several vertebræ will be, to diminish, if not altogether stop, the jarring and friction between the diseased surfaces, which tend so greatly to aggravate the morbid action. An incipient abscess will, therefore, be in a comparatively more favorable condition for undergoing cure by resolution. Accordingly, it may be supposed that the diseased process will sooner or later cease; that the abscess will be obliterated; and that the confronting surfaces of the partially destroyed vertebræ will come into apposition. The consolidated posterior segment will preserve the vertebræ at rest, like splints applied to a fractured bone; the surfaces may therefore be expected to unite; with, perhaps, remnants of the bodies of several adjoining vertebræ all fused into one. Such is a description of *true* ankylosis.

Spurious ankylosis.—This term is applied in reference to the joints in general, to that kind of union between the surfaces, after disease, in which the bond consists either wholly of fibrous structure, or of that combined with osseous matter. In the spine it denotes that the posterior surfaces of the vertebræ alone, including the laminæ and various processes, are soldered by bone, while the surfaces of the bodies, partially consumed by the caries, are apart; and are connected above and below by the remains only of the walls of the obliterated abscess.

The writer had an opportunity of exhibiting, at a meeting of the Pathological Society,[1] a series of five different specimens of vertebræ united by bone after caries, and in which the ankylosis was partial. The appearances were essentially the same in all. Down the whole length of the posterior segments of the affected vertebræ, perfectly solid ossific union could be traced between the margins of the laminæ and the oblique processes, including their articular surfaces; and it was so firm and general, that all mobility was destroyed. But no similar union had taken place on the fore part. The bodies had been destroyed to different degrees, and gaps of various width separated them; so that the continuity of the spine as a column, depended wholly at the diseased part on the posterior segment. The amount of separation between the surfaces of the bodies was owing to two distinct causes; in some of the specimens, the distance at which the surfaces were apart was to be accounted for principally by the quantity of substance lost through the carious ulceration; in others, it was obviously consequent mainly on the too great obtuseness of the angle at the seat of flexion, and the inability of the surfaces, from the spine having become fixed, to approach closer to each other.

The importance, in a practical view, of keeping this distinction between the two forms of ankylosis in mind is obvious.

1. It bears on the question, as to which position of the spine, during the treatment, is most favorable for obtaining solid union between the surfaces at the close of the disease. The friends of a young patient are naturally much distressed when they see the rapidity with which the spine becomes bent, and they would fain induce the surgeon to employ measures to keep the column straight. They are not aware that a certain amount of deformity is a necessary condition of cure in this dangerous disease. Loss of substance in the fore part of the column is inevitable: the destroyed portion cannot be replaced: the only way by which a cure can be effected, is by the upper and lower portions coming into apposition, and uniting as a broken bone would do; but that approximation and union can only take place by the spine becoming bent at an angle more or less acute. Hence, even if the treatment by extension were safe—which it is not—a sufficient argument against it would be, that in the event of its being carried out, the only union obtained would be in the posterior segment, and a permanent gap would be left in front.

2. It is sometimes advantageous for the surgeon to be acquainted with the proceedings of quacks. Bone-setters and others frequently undertake to straighten the spine in cases of angular deformity; and as they occasionally have a certain temporary success which gains them reputation, it is more necessary to understand what they do, and at what a risk. They will take, for example, a young man who has a prominent hump in the dorsal region, consequent on disease which he may have had in childhood. By confining him in the recumbent position, employing mechanical means to stretch the back, and putting him on physical exercises, not forgetting to manipulate the projecting vertebræ sufficiently often, the spine may be made straighter, and the hump less distinct.[1] The quack will probably represent that the cure has been effected by his reducing the dislocated bones at the angular projection. But it is obvious that the apparent improvement has been brought about wholly by the extension of the sound portions of the spine above and below the apex of the angle. Each of these portions, besides being inclined from before backward, is curved; and it can be easily understood that, by restoring them to a vertical line, the whole column will be rendered straighter, and the protuberance less distinct. But it is not to be expected that the improvement will last. As no change can be made in the relations of the vertebræ at the seat of ankylosis, and their surfaces, in conformity with the angle they form, are placed obliquely, the longitudinal axis of the upper and lower portions respectively must likewise be bent in reference to each other. Hence the spine will soon return to its former condition. But it is the danger of the treatment which constitutes the chief objection. And that arises from its being impossible to know beforehand what is

---

[1] Path. Trans., vol. i., p. 328.

[1] See a series of casts taken from patients who had undergone treatment by mechanical extension for angular deformity, contained in the Museum of the Middlesex Hospital.

the exact kind and degree of union that may have taken place at the seat of disease, or what may be the state of the abscess. If the cavity of the abscess has been obliterated, and the former communication between it and the carious bodies closed, and if the ankylosis has been perfect, so that no remnant of the disease has been left, the treatment, however rough, might do no harm, if it did no good. But the results would be disastrous, if the ankylosis were spurious, and the walls of the abscess were the only connection between the upper and lower portions in front. Owing to the union between the vertebræ at the back, the mobility would be destroyed, and it might be inferred that the ankylosis was perfect; yet the osseous bond might not be sufficiently strong to resist the violence sometimes employed in endeavoring to straighten the spine, by ignorant practitioners.

A friend related to the writer the following case, and also showed him the preparation connected with it. A young woman had caries of the lower cervical and upper dorsal vertebræ, from which she recovered, so as to be able to resume her employment. The angular deformity being considerable, she applied to a quack, who promised to make the spine straight. The treatment consisted chiefly in employing mechanical means to stretch the neck. While increasing the power one day, there was an audible snap, with sudden pain. The patient was found immediately afterwards paralyzed from the neck downwards, and in a few days she died. It was found at the post-mortem examination that there was an abscess, nearly obliterated, in front of carious vertebræ; and that the walls of the abscess had been extensively torn from their connections with the bones. The spinal cord was diffluent near the seat of injury. It cannot be doubted that when the force of extension was increased and the snap heard, the bony connections of the posterior segment of the vertebræ had been broken, the walls of the abscess detached from the bodies in front, and the spinal cord ruptured.

Psoas and Lumbar Abscess.

The abscesses hitherto treated of have been supposed to have stopped growing before they attained a large size; they have remained dormant, or been removed by absorption. The next to be considered are those which have progressively enlarged, and travelled long distances to evacuate their contents externally. Owing to the great dimensions which the latter commonly acquire, and to their cavities communicating with the vertebræ while still in a state of disease; they are especially dangerous in their consequences; they are, indeed, the most frequent causes of death in spine disease.

A spinal abscess, at its commencement, lies upon the carious vertebræ, filling up the angle in front. It is favored in taking that position by the bend in the column, which has the effect of relaxing the structures on the fore part, and facilitating the accumulation of fluid. For the same reason abscesses will sometimes increase to a large size in the dorsal region without producing undue pressure on the roots of the lungs. As the pus accumulates, it is prevented by the portion of spine which forms the upper side of the angle overhanging it, from ascending; it cannot proceed backward, owing to the thickness of the structures;[1] it would be difficult for it to make its way down the front of the bodies; accordingly, the ordinary course which an abscess takes when it enlarges is downward, by the sides of the bodies of the vertebræ. Sometimes the main sac bifurcates, one branch descending along the right and the other along the left side. In the thorax, the walls of the abscess are covered in front by the costal pleura; in the abdominal region by the parietal peritoneum. When the abscess is connected with diseased dorsal vertebræ, it encounters in its descent the diaphragm. But that barrier is overcome by a particular process. As the abscess comes into contact with the diaphragm and compresses it, adhesive inflammation is set up in their respective surfaces; the consequence is, that they become united over a considerable area; an opening is next formed by absorption within the boundaries of the adhering structures; the abscess then protrudes; and extravasation of pus at the margins is prevented from taking place by the firm union of the parts encircling the opening.

Psoas abscess.—When the abscess has thus perforated the diaphragm and gained its abdominal side, it comes into relation with the heads of the psoas muscle. That muscle arises by one set of fibres from the sides of the bodies of the vertebræ, by another from the roots of the transverse processes; and stretched across both origins in front are the ligamenta arcuata. As the abscess, therefore, travels downwards, it has to pass through a narrow strait; it is prevented from enlarging on the fore part by the resistance of the ligamenta arcuata, and at the back by that of the spine and lowest rib; hence, in order to proceed, it has to force its way in the line of the psoas muscle. That, however, can only be done by penetrating into its interior. It accomplishes this, in the first place, by inserting its most advanced part, like a wedge, between the two origins; it then splits and distends the fibres, so as to form a cavity for the reception of the pus; the muscular fibres become incorporated with the walls of the abscess; and the psoas at length is converted, more or less thoroughly, into an abscess. But the muscle charged with pus does not expand equally in every direction. The fascia iliaca forms a kind of sheath for it; and this, being particularly strong on the inner side and united firmly to the brim of the true pelvis, prevents the growth of the abscess inwardly. On the outer side, however, the connections are loose; and there enlargement takes place freely. The abscess now chiefly occupies the hollow between the united fibres of the iliacus internus and psoas muscles, on the inside, and the crest of the ilium on the outside. When the advanced part reaches the level of Poupart's ligament, a certain retardation occurs; and then a bulging will be observed along the line of the flexure of the groin. The abscess now perforates the abdominal walls in the same way as it formerly did the diaphragm. And the opening is invariably at one place, namely, behind Poupart's ligament, between the united tendons of the iliacus internus and psoas muscles, and the anterior inferior spinous process of the ilium. The situation corresponds to the point of junction of the outer with the middle third of Poupart's ligament.

---

[1] The writer does not remember more than one case in which a spinal abscess in the dorsal region opened directly backward. There were two orifices near the projecting angle. The pus flowing from them had bubbles of air mixed with it; and it was noticed that these were drawn within the openings in inspiration and expelled in expiration.

Before the protrusion takes place, there will be a certain amount of thickening and condensation of the connecting tissue in the groin—a consequence of the inflammation excited by the near approach of the abscess—and a provision at the same time for strengthening its walls when it does emerge. On the abscess actually escaping, it will be suddenly relieved from a considerable compression to which it had been subjected in the interior; and it is from that cause, probably, that it increases rapidly in size as soon as it appears outwardly. The enlargement is sometimes greatest in the groin, and for a short way down. But it is more common for the abscess to descend for some distance on the thigh; and the direction then varies. Owing to the walls abutting at the commencement of its course against the origins of the sartorius and tensor vaginæ femoris, and their opposing its progress outwardly, the line which it most frequently takes is inward and downward, along the sartorius; and it often accompanies that muscle to near the knee. Sometimes, however, soon after its appearance in the groin, it turns sharply inward to occupy a space over the adductor muscles. In a comparatively rare set of cases it bends outwardly. The least frequent direction is straight downward. Occasionally, the abscess divides at the groin; one portion going inwardly and the other outwardly.

"Neck" of the abscess.—It seems appropriate, on the analogy of hernia, to call the narrow part of the abscess where it passes through the abdominal parietes, its "neck." It may be true that, when an abscess has been formed in the thigh, consequent on matter descending from a diseased portion of the spine, it is free, like others arising differently, to secrete additional pus from its own pyogenic membrane, or to absorb it; yet it would appear that abscesses originally spinal, are mainly dependent on the parent one. Now, the channel of communication between the well from which the fluid is drawn, and the sac or reservoir below, is constricted at the neck more than elsewhere. It will depend, therefore, greatly on the width of that aperture as to whether the abscess in the thigh be abundantly or sparingly replenished from above. In general there is a disposition in the opening to contract: although it has never, according to the writer's knowledge, become entirely closed. The degree to which the narrowing has gone, will commonly be judged of pretty accurately by the feel of the parts when the contents of the abscess have been squeezed upwards, and then when uncompressed, and comparing them with the condition of the corresponding parts on the sound side. Occasionally both the neck and the channel leading from it to the abscess are constricted to such a degree that no traces of them can be found: the collection appears circumscribed; and a question arises as to whether it be really connected with the spine. The surgeon may, therefore, have recourse to another mode of examination; if he bandages the abscess firmly for a few days, it will be seen to have had the effect of reducing the swelling considerably in size; let him next leave the abscess without bandages, and permit the patient to be in the upright position; he will soon find that the swelling has returned to its original dimensions—thus showing that the channel was pervious, and that the pus could be passed along it, to and fro.

Lumbar abscess.—It was stated formerly, when describing the process by which a spinal abscess, originating in the dorsal region, made its way through the diaphragm, that the passage was effected through a narrow opening, bounded in front and outwardly by the ligamenta arcuata, behind by the lowest rib, and on the inside by the bodies of the vertebræ; and it was added, that the abscess continued its descent by penetrating the psoas muscle. At the point where this obstruction is met with, and where the ribs cease to form an obstacle to the passage of the abscess backward, it occasionally perforates the abdominal parietes, and presents itself in the loins as a "lumbar" abscess. In some cases the whole abscess takes that route, but in others only a part; so that the lumbar is merely an offshoot of a psoas abscess. Again, a lumbar abscess may be in connection with diseased upper lumbar vertebræ: just as may be the case with a psoas abscess. The lumbar abscess perforates the quadratus lumborum, and it appears under the skin on the outside of the sacro-lumbalis muscle. In its progress posteriorly the abscess meets with opposition from various dense fasciæ and tendinous expansions; which deflect its walls, and cause it to assume outwardly a broad and flat appearance, with slight elevation.

Spinal abscess in the neck.—Disease affecting the articulations between the two uppermost vertebræ of the neck, the atlas and axis, is characterized by certain peculiarities which entitle it to be treated of separately: its consideration will, therefore, be postponed to the end of the article. When any of the inferior cervical vertebræ are the subjects of caries, a collection of pus will form on their fore part, as in the spine generally: but instead of the matter accumulating there, and forming a prominent swelling which might compress the trachea or œsophagus, or dropping downwards, it is deflected laterally. Hence the abscess appears outwardly on one or both sides of the neck, inclining somewhat posteriorly.

Varieties in spinal abscesses.—It is proper to mention some exceptions or anomalies met with in abscesses in different parts of the spine.

1. In describing the first stage of the formation of psoas abscess, it was stated that the sac occasionally bifurcated; one branch descending along one side of the bodies of the vertebræ, and the other along the other. Cases in which both have arrived and pointed at the groin are extremely rare. Dissection sometimes reveals the fact, not ascertained during life, that while an abscess, on one side, ran its whole course and discharged its contents on the thigh, another, on the opposite side, stopped short about midway. In every case an examination ought to be made to ascertain whether there be two abscesses or only one.

2. It is not uncommon, in a case of psoas abscess, for the collection of pus to be arrested in its progress downward, just above Poupart's ligament, or when it is lying on the venter ilii. It may then increase in size and become a prominent, globular swelling, with distinctly defined boundaries.

A young girl, fourteeen years of age, had disease in two or more of the central dorsal vertebræ; it had caused great angular deformity, and, for a certain period, paraplegia; at length a globular swelling, visible to the eye, formed in the right iliac region. After remaining stationary for a short time, it began to diminish; then it got gradually smaller, till, after the lapse of several months, it had entirely disappeared, so that no trace of it could be found. The local treatment consisted in the continued application of the tincture of iodine. Eventually the patient's health was quite restored; the deformity alone remaining.

3. When a spinal abscess, in descending, reaches the hollow of the ilium, instead of pursuing its course downward, it occasionally turns sideways, mounts over the crest of the ilium, and discharges its contents, by one or more openings, over the glutei muscles. The same thing is sometimes met with in connection with lumbar abscess. The occurrence is more frequent in children than in adults: a difference which may be accounted for by the relatively small size of the pelvis in the former.

4. Sir B. C. Brodie has described certain cases in which part of the contents of a psoas abscess, when lying in the iliac region above Poupart's ligament, has made its way into the spermatic canal, and so appeared at the external abdominal ring, like an inguinal hernia.[1]

The writer has witnessed a similar case, in which the tumor had some resemblance to a reducible hernia. Along the flexure of the groin, and for some distance above, there was general fulness and induration of the structures. At the external abdominal ring, and for a short distance below, in the line of the spermatic cord, there was a circumscribed swelling, which became more prominent when the patient coughed. The contents of the supposed sac, however, were quite soft and compressible. The man was not aware that he had disease of the spine, having come to the hospital for some comparatively trivial complaint. On turning to the back, there was an absence of any distinct projection of the spinous processes; all that could be perceived was a slight arching backward of the vertebræ in the lumbar region, which was in contrast with the hollow naturally existing there. The chief diagnostic symptoms were, well-marked rigidity of the column at the loins, and natural flexibility elsewhere. Shortly after his admission he rapidly got worse; the abscess in the groin broke; and, on his death, the bodies of three lumbar vertebræ were found carious and surrounded by pus.[1]

[1] On Diseases of the Joints, p. 267.

5. *Contents of spinal abscess discharged by the lungs.*—It has been already stated that when abscess forms behind the posterior mediastinum in connection with diseased dorsal vertebræ, it is generally prevented, by the bending and receding of the spine, as well as by the cavity emptying itself downwards, from enlarging to such a degree as to press on the roots of the lungs and impede their functions. But a danger of another kind is to be apprehended from the proximity of the collection of pus to the lungs: inflammation is apt to spread from the pleura costalis, which covers the walls of the abscess, to the pleura pulmonalis and substance of the lungs: pleurisy or pneumonia, or both combined, may then be excited, and death may ensue. A different result, however, may be looked for, in a few exceptional cases: namely, the evacuation of the abscess through the lungs. The process by which that is effected is the same that has been described in explaining how an abscess perforates the diaphragm in passing from the thoracic into the abdominal region. It is the same also as the process by which an abscess of the liver discharges its contents through the lungs. Firm adhesion is first established between the walls of the abscess and the surface of the lungs; next in some central part within the area of these adhering structures, an opening by absorption is made, having the margins secured by the surrounding adhesion; this opening brings the interior of the abscess into communication with lung substance, which becomes condensed in the neighborhood; a tunnelling is commenced through the latter until a large bronchial tube has been reached and opened; then the pus is coughed up and expectorated.

The writer was consulted in the case of a boy affected with angular deformity, the apex being formed by the spinous processes of the fourth and fifth dorsal vertebræ. He had been confined to bed at the commencement of the disease, five years before; he had since then been strong and active; and the object of the consultation was merely to ascertain whether anything could be done to improve his figure. During the interview the patient took from his pocket a small box containing fragments of bone: and these he said he had coughed up, together with a large quantity of matter, when his illness was at the worst. The structure of the pieces resembled that of the bodies of vertebræ; they were generally cancellous, but had here and there portions of cortical layers upon them; they were four in number, irregularly cube-shaped, the sides measuring, on an average, from three to four lines. It was supposed that they had lain loose in an abscess at the seat of the deformity, and been expectorated.

6. *Abscess opening into intestine.*—It is not uncommon for abscesses in the abdominal region, with whatever viscus they may be connected, to empty themselves into some part of the intestinal canal if they come into contact with it. For example, abscess of the liver frequently terminates in that way.

The following is a brief notice of a case in which a spinal abscess communicated with a portion of intestine, and in which not only did the matter of the abscess pass into the bowel, but the contents of the bowel discharged themselves by the abscess. The patient was a girl, thirteen years of age, who had acute angular deformity at the centre of the dorsal vertebræ, and a psoas abscess of several months' duration on the left side. The abscess reached down to the knee; the external opening being over the inner condyle of the femur. As a proof that the abscess admitted some of the contents of the intestines into its interior, the patient, during the writer's visit, picked from the orifice the skins of one or two peas, and a bit of undigested stalk of greens, which she had been lately eating.

7. *Spinal abscess discharging its contents by the urinary bladder.*—

An under-gardener, 24 years of age, had angular deformity; the most prominent spinous process being that of the seventh dorsal vertebra. He could not tell when the disease began; and as he had never missed a day's work on account of it, he had reluctantly left his situation to become a patient. By carrying the fingers deeply in the direction of the psoas muscle, a large abscess could be distinctly felt. He remained in the hospital two months, during which no perceptible change occurred. At the end of six months he returned, having worked at the spade the greater part of the intervening time. He stated that a week before, he had slight trouble in passing his water, and shortly afterwards he voided a large quantity of matter of a yellow color, along with the urine. That he had continued to do since; but latterly the proportion of the pus to the urine had gradually diminished. During his stay in the hospital, about a third of what was passed consisted of pus. No trace of the abscess in the iliac region, which had been repeatedly felt before, was discernible. The patient left the hospital of his own accord, a fortnight after his readmission; and he could not be heard of afterwards.

Diagnosis of spinal abscess.—One of the most frequent causes of uncertainty in distinguishing abscesses connected with caries of the vertebræ from other swellings in the same locality, is the insidiousness with which spinal disease, as already stated, often commences and proceeds.

---

[1] See preparation in the Museum of the Middlesex Hospital.

The following is an example, being that of a psoas abscess mistaken for a hernia. The patient was a young man, son of a large farmer, fond of hunting, and he had regularly followed the hounds till a few days before coming to town for consultation. He had observed, for a week, in his left groin, a swelling which his medical attendant told him was a rupture, requiring a truss. In the flexure of the groin there was an oval tumor, of well-defined shape, and resembling a hernia, except in the point at which it emerged. It came out behind Poupart's ligament, an inch and a half externally to the part at which femoral hernia descends; in other words, it protruded at the place where psoas abscess appears when it passes out upon the thigh. Above the ligament, and in the iliac region generally, there were fulness and induration. On examining the back, no distinct protuberance of any of the spinous processes was visible. But in the loins there was a perceptibly greater bulging backward of all the vertebræ than is natural, without undue prominence of any individual bone; the lumbar vertebræ were likewise abnormally rigid; the only free mobility being in the dorso-lumbar region. The patient owned that, several months before, he had received an injury in the lower part of his back; but it was so slight that he had not given up any of his active pursuits for it. The dangerous nature of his illness was explained to him. He was loth, however, to forego his hunting. Ere long the abscess enlarged, broke, and discharged a large quantity of pus. When last heard of, his recovery was deemed hopeless.

An abscess originating in caries of the lower lumbar vertebræ and extending it may be to the sacrum, is liable to spread laterally on the wing of the ilium, and to rise above the level of the crest. A swelling of that kind, if it be on the right, may be confounded with a cæcal abscess. Or if it surmount the crest and discharge its contents backward and downward, the movements of the hip will be disturbed; and it will be supposed to have originated in morbus coxæ. The diagnostic symptom most to be relied on in these doubtful cases, is the degree of flexibility observable in the lumbar region.

A tumor of medullary cancer is not unfrequently mistaken, according to its situation, for either a lumbar or psoas abscess. The uncertainty will be increased if the cancer has invaded the spine, and by converting part of it into its own morbid structure, has caused the column to become bent. Again, it is the peculiar nature of this kind of carcinoma to throw out globular projections on the surface, resembling greatly the pointing of an abscess; moreover, the feeling of elastic resistance at the apices of these lobes, is so much like that of undulation of pus within an abscess, that a mistake in diagnosis is very apt to be made.[1]

The writer had lately under his care, in the hospital, a female of middle age, who had lateral curvature of the spine from girlhood; and in whom the hump was so prominent and abrupt that it might be mistaken for angular deformity from caries of the vertebræ. She was admitted for a tumor that occupied the inner side of the left wing of the pelvis, and was on a level, at its anterior part, with the crest of the ilium. An oval-shaped, projecting lobe, in course of time, formed on its most depending face, near Poupart's ligament; and the feeling communicated to the finger, when examining that part, bore the greatest resemblance to what is conveyed by pus, when near the surface of an abscess. The subsequent progress and termination of the case showed that the tumor was one of medullary cancer.

Treatment of external spinal abscesses.—In discussing the question of the two kinds of ankylosis of the spine, the true and false, reasons were advanced for believing that, when an abscess at the seat of disease subsided, to give place to ossific union, it was to the arrest of motion caused by the consolidation of the posterior segment of the spine that the beneficial effects were principally to be ascribed. In such cases, the abscess is confined within the range of the rigid portion of the column. But when unfavorable influences interfere with the termination in ankylosis, and the abscess enlarges by extension of its walls downward, it gets beyond the bounds of the inflexible part, takes its place in movable structures, and consequently loses the advantage which rest is calculated to confer. Thus progressive increase goes on, and the abscess eventually presents superficially, where, of course, exposure to the bad effects of motion is worse. These considerations enforce the propriety of employing, in the management of such abscesses, every available means for procuring perfect rest.

Another general observation applicable to the subject is, that in common with other collections of pus having their origin in diseased joint-structures or diseased bone, it is the continued irritation kept up in the walls of the abscess and adjacent parts, by the presence of the carious bones and ulcerated surfaces, which chiefly leads to the fresh formation of pus; whence all measures designed to forward amendment in the abscess, ought to be accompanied with others directed to improve the condition of the spine at the original seat of disease.

---

[1] See article Cancer, Vol. I., p. 286.

An additional remark may be made, which still applies to large abscesses whether originating in the spine, hip, or other joints, when diseased. It relates to the contrast observed in the condition of the patient, before and after the evacuation of the contents: either when the abscess has burst spontaneously, or been opened by the lancet. It is constantly seen in practice that an abscess of extraordinary size will often remain for many weeks together perfectly quiescent; perhaps enlarging a little at one time, and diminishing a little at another; the patient being all the while free from constitutional disturbance. But if the abscess point and break, or the surgeon open it, and the puncture does not heal, but the matter continues to run, an important change will soon occur. The unfavorable symptoms come on at various periods in different cases. It may be expected that within a few days the quantity of pus from the abscess will greatly increase: that it will become thin, and perhaps variously discolored. At the same time also, the patient will sicken, his pulse will be quickened, his skin hot, with occasional profuse perspirations; the fever will be hectic, attended with gradual wasting and increasing debility; the liver will probably enlarge by fatty degeneration; and he will die exhausted by the combined effects of the purulent discharge and the fever. (See article HECTIC, Vol. I., p. 126.)

Now it is the anticipation of that change being brought on by evacuating a lumbar or psoas abscess, that chiefly leads to hesitation and delay in the treatment. The surgeon may rest, for a while, on the hope that he may possibly succeed in dispersing the collection by resolution: he therefore keeps the patient rigorously at rest; supporting the strength by tonics and diet; and he applies assiduously tincture of iodine to the back, at the seat of disease; to the side, in the course of the abscess; and to the swelling itself; he thinks that if the abscess be not altogether removed by such means, its size will be diminished, and the walls converted into a fitter condition than before for the operation of puncturing. His expectations, however, will probably not be answered favorably. He may perceive that at some particular part there is an appearance of acumination, and he is desirous of averting spontaneous opening. Necessity, therefore, seems to compel him to adopt the plan of tapping the abscess and drawing off the pus. It may be supposed that the proceeding has been carried out in the most approved way, with all the precautions commonly urged (see article ABSCESS, Vol. I., p. 333); yet the almost inevitable termination will be, a bursting forth of the matter, from the temporarily closed openings artificially made, and an established discharge from the abscess, with all the uncontrollable ill-effects apprehended as the sequel. [König[1] claims that the successful treatment of lumbar and psoas abscess depends upon providing for perfect drainage; and for that reason it is desirable to have an opening in the lumbar region. For this purpose he makes a counter opening, when it is possible, in the back after incising the abscess, pointing in front.] These considerations prompt us to greet with welcome the valuable labors of Professor Lister, and of others, in their present active endeavors to improve this part of surgery.

[Gibney found that in 295 patients suffering from Pott's disease, paralysis occurred in 62 during the course of the affection. This complication is much more frequent when the disease is in the upper part of the canal than in the lower. Out of 189 cases of disease in the upper dorsal and cervical regions, paralysis occurred in 59; while only 3 were recorded with paralysis among 106 cases of caries in the lower portion of the spine.

Recovery from the paralysis appears to occur in the greater number of the cases. Dr. Gibney states that out of 58 cases with paralysis 13 died, 28 recovered from the palsy, 15 remained unrelieved at the time of the report. Some of the recoveries from the paralysis took place after the patients had been paralyzed four, five, and ten years, after symptoms of apparent myelitis.

Paralysis is rarely, if ever, an early symptom in caries of the spine. It is sometimes partial. In almost all the reported cases the paralysis was preceded by paresis.

In many there was an increase in the reflex irritability, and in some, muscular tremor or muscular spasm giving rise to rigidity of the limb.[2]

Paralysis is due to an extension of the inflammation of the bodies of the vertebræ to the dura mater of the cord, and the formation of a pachymeningitis; the cord becomes compressed, and a myelitis results from extension of the inflammation.

It seems incredible that recovery can take place after extensive degenerative changes have taken place, but such is undoubtedly the fact, as has been demonstrated by pathological evidence afforded by patients who have recovered from paralysis and subsequently died.[1]

---

[1] Berl. Klin. Woch., Feb. 16, 1880.]

[2] Journal of Nervous and Mental Disease, April, 1878, p. 254.]

Probably paralysis also results in some cases directly from the pressure upon the cord by the contents of an abscess, which has extended to the dura mater but not yet occasioned a myelitis.[2] The symptoms diminish or disappear as the fluid escapes in another direction and the pressure is removed.

Echeverria claims that paralysis may also result from the thickening of the dura mater, without suppurative or inflammatory change in the cord proper. In some rare cases paralysis is caused by the pressure of a necrosed fragment of bone.

The myelitis which arises in Pott's disease is of course local, but ascending degeneration of the posterior median columns may occur secondarily, and also a descending change in the lateral, and occasionally in the anterior columns.[3]

Affection of the Spinal Cord from extension of the Disease.

When we consider the delicacy of structure and constitution of the medulla spinalis, and its contiguity to the centre of so destructive a morbid action as caries, we may be surprised that its functions are not lost in a greater number of cases than experience shows to be the fact. Yet, as the surgeon has no means of foretelling, in any particular patient, whether the cord will be affected or not, he is kept in constant apprehension.

Several circumstances combine to protect the cord from injury. First, in proportion as the spine falls forward, and forms an angle at the seat of disease, the abscess is propelled to the front, and the chasm between the bodies is closed behind, so as to prevent the pus from having access to the vertebral canal. Secondly, it is within the posterior segment of the spine that the cord is contained; and it has been formerly shown that, while the anterior segment, composed of the bodies, is the special seat of caries, the posterior is exempt from disease, and has a reparative or defensive action carried on within it: the cord, it may therefore be inferred, will not be injuriously affected by such kind of action. Thirdly, it might justly be feared that when a part of the spine had been destroyed by caries, and a deep gap formed between two or more of the bodies, the column would be so much weakened that it would be liable to be broken by any slight injury; and that the cord would therefore be crushed and deprived of its functions. But it has been already pointed out (supra, p. 307), that when caries attacks the vertebræ in front, a process of agglutination and consolidation, terminating in firm osseous union, is immediately set up in the posterior surfaces of the same bones. Hence, in proportion as the spine yields to the pressure of the superincumbent weight, and the upper part tends to fall forwards, that movement is restrained and moderated by the opposition of the structures behind, which have thus been endowed with increased strength. Accordingly the angle at the seat of disease is formed in a slow, gradual manner, without jarring or abruptness; and the cord becomes accommodated to its novel position without loss or impairment of its functions.

Before describing the morbid condition of the cord from which paraplegia ensues, it may be interesting to notice certain considerable changes in its structure which are connected with the deformity, but which do not involve any deprivation of its functions. When a large portion of the front of the spine has been removed by caries and the surfaces have united, not only will the characteristic angle be formed, but the column will be considerably diminished in length at the seat of disease. This shortening is to be attributed to the loss of substance which the affected vertebræ will have sustained, and to their having collapsed into a comparatively small size before union. The vertebral canal, and the cord contained in it, will necessarily participate in this bending and shortening, and be accommodated to both. Now it may be inferred that, to bring about the adaptation adverted to, a succession of minute interstitial changes in the substance of the cord must have been wrought during the progress of the deformity; that certain portions of the material will have been abstracted and their places not filled up; and that other portions will have been arranged in a different order from at first. It is not found, however, that either the atrophy, or novel arrangement of the nerve substance, has a prejudicial effect on the functions; for these will remain entire, however extreme the deformity. The explanation is founded on a well-known law in the pathology of the brain and cord; namely, that changes of extraordinary magnitude may be effected

---

in their structure by encroachments of various kinds, without the sacrifice of their functions, on condition that the intrusions are made slowly and gradually. Remarkable examples of the kind, connected with atlo-axial disease, will presently come before us (infra, p. 324). Moreover, every case of lateral curvature furnishes examples.

Disorganization of the cord; paraplegia.—From what has just been stated, it will be perceived that the change of structure in the cord which causes paralysis of the lower extremities, is not the mere alteration of its figure or size consequent on the angular deformity. It consists in a conversion of a portion of its substance into a new morbid tissue. A certain part of the organ, adjacent to the seat of caries, undergoes a process of breaking-down of its texture; the most conspicuous effect of which is a softening, approaching to liquefaction, of its columns and gray matter. If the diseased part be tapped with the finger, it will readily yield to the slightest pressure; if a stream of water be allowed to fall gently upon it, the soft substance will be washed away, leaving the connecting tissue. When the cream-like matter is examined with the microscope, it is observed to be made up of innumerable fragments of nerve-tubes, granules, oil-globules, and amylaceous cells, the débris of medullary tubes and ganglion-cells. A tinge of yellow pervades the softened and neighboring parts. The membranes do not commonly present any decided signs of having been implicated, nor is the vascularity much altered.

It will depend on the depth to which the morbid change reaches, in any particular case, as to the functions of the cord which will be abolished. We owe to modern discoveries the knowledge of the fact, that to the anterior column, from which the anterior roots of the spinal nerves arise, belongs the power of controlling the muscles; and that to the lateral column, from which the posterior roots arise, belongs sensation. Hence if the disease penetrate only so far as to destroy one column, leaving the other sound, we may anticipate that the function pertaining to the disorganized column will alone be lost.

Experience proves that, in paraplegia caused by disease of the spine, motor power is much more frequently destroyed than sensation; and so general is this fact, that it may be regarded as a comparatively rare thing for both motion and sensation to be lost simultaneously. As to the reverse kind—abolition of sensation with motor power remaining—it is doubtful whether such a variety was ever met with.

When we consider the relative position of the different columns of the cord to the centre of disease in the spine, we shall at once perceive why motion should be first destroyed. The anterior column, on which motor power depends, is separated from the bodies of the vertebræ only by the theca vertebralis and the other membranes of the cord: hence it may be expected that, when the morbid action proceeds backward, this column will be deprived of its function before any other. And its liability to be so involved will be increased by the compression to which it is peculiarly subject from the bending of the spine, as it forms an acute angle at the part.

Moreover, if we trace a filament of an anterior root to its origin, we shall find that, as it is about to join the cord, it subdivides into numerous minute radicles, and that these lose themselves almost imperceptibly on the *surface* of the anterior column. If, on the other hand, we take a filament of a posterior root, we shall observe that it continues as a single fibril up to the cord; that when arrived there, it dips bodily, without subdivision, into the fissure between the posterior and lateral columns; that while in the fissure, it pursues an unbroken course to the bottom; and that its actual termination is in the *deepest* part of the cord, where the central cineritious matter is situated. It appears, therefore, that the part of the medulla appropriated for sensation must be in the internal, well-protected recesses of the organ; where it is less likely to be reached by disease invading the exterior, than the column of motion, situated more superficially.

It will depend on the height in the spine at which the cord is diseased as to the extent of the body that will be paralyzed. If the disease be in the lower lumbar vertebræ, that is, below the termination of the cord, there may be an absence of paralysis: unless, as occasionally happens, the products of inflammation have extended upward, to involve the medulla above. In not a few cases, one extremity is more completely deprived of motor power than the other. Comparing the paraplegia resulting from disease with that from injury, it is remarkable that the former is seldom accompanied with loss of command over the bladder or rectum; and that when these organs are affected, it is commonly in a slight degree. Retaining sensation, the patient may have an urgent desire to pass water, but he will be unable to do so, and will require the assistance of the catheter. Again, the stools may pass at one time involuntarily, at others consciously. In general, the torpidity of the bowels renders it necessary to give aperients frequently.

The cases are comparatively rare in

which the loss of power in the limbs leads to the formation of bed-sores. If the patient be an adult, who suffers much pain at the seat of disease, making it difficult to shift his position, there will be danger of such sores; but not so great as in cases of paraplegia from fracture of the spine, when the feces and urine pass involuntarily, and the hips are constantly sodden in the filthy moisture. In a young person, on the other hand, whose body is light, in whom sensation has not been lost, and who can feel the irksomeness of lying for a long time in the same posture, we do not look for sores; he can turn himself by the use of his arms, change the position of his hips, and thus avoid the bad effects of pressure.

Spasmodic actions of the paralyzed limbs.—When the lower extremities are entirely bereft of voluntary power, they are subject, nevertheless, to convulsive actions; through some obscure morbid influence acting on the distal portion of the spinal cord cut off from connection with the brain. The spasms are the same that are witnessed when the cord has been destroyed by violence, or by the encroachment of tumors, ramollissement, etc. A frequent form of the attack consists in a sudden jactitation of one or both legs. While the patient is lying quiet, the limbs will suddenly be drawn up; they will be bent both at the knees and hips—so that the heels will come in contact with the back of the thighs, and the knees with the abdomen: the flexor muscles will then relax, and the limbs will fall straight, as before. In such cases the spasms are of short duration; but they may be repeated with great frequency, so as to cause much distress. A different form consists in the legs being drawn up, and then remaining bent. In these cases, the limbs and body will be so rigidly fixed, that the patient may be moved about in bed, in one mass, like a log of wood. Cases will be met with in which both the above forms are presented, at different times, in the same patient. The spasmodic actions, whether clonic or tonic, are apt to be excited by certain irritants; thus tickling the soles of the feet, pinching or pricking the skin, the act of moving, will bring on the sudden startings, or will aggravate the contractions of the rigidly bent limbs. Micturition and defecation sometimes, but rarely, excite attacks. Yet they frequently come on without any perceptible cause of irritation. When the patient is drowsy and about to drop asleep, he is peculiarly subject to be awakened by the limbs jumping.[1]

The pain occasioned by the spasmodic affections is sometimes excessive. In certain cases it equals, if it does not surpass, the agony of tetanus in its worst form: happily, in the majority the suffering is moderate and endurable. Sometimes, when the convulsions are strong, they shake the whole body, and communicate a painful jar to the diseased vertebræ. Again, if the patient have bed-sores, the concussion produces friction of the hips against the bedding, and that aggravates the ulceration or sloughing. When it is attempted to subdue the spasms by applying splints to the limbs, or by bandaging the leg that is affected to the one that is quiet, and fastening them, when thus secured, by India-rubber tubing to the bedposts, the plan commonly fails; the skin is liable to be frayed, and the pain is not diminished. There is no particular medicine that can be relied on for overcoming the convulsions. Good effect sometimes follows injecting morphia under the skin.

Diagnosis.—As intimated before, paraplegia consequent on caries of the vertebræ does not differ materially from that which may be caused by morbid affections of the cord, of various distinct kinds. The principal diagnostic symptom in spinal disease is, doubtlessly, the angular deformity. Observation shows that paraplegia of this kind does not occur till late in the disease, after the bodies have been partially destroyed. Consequently, if there be no distinct projection of the spinous processes, or rigidity of the vertebræ, to indicate excavation of the column, it is probable that the paraplegia depends on some other morbid affection. Again, palsy arising from caries is commonly distinguished by motor power being abolished while sensation is unimpaired. If the reverse be found, namely, loss of sensation with retention of motor power, it may be inferred that the cord is encroached upon by some morbid growth advancing from behind forward.

Prognosis in paraplegia.—Experience proves that, in paraplegia from spinal disease, restoration of the lost powers of the limbs is not uncommon. The mode in which recovery takes place appears connected with the bending of the spine at the seat of the caries. It has been previously stated that, in the majority of cases, the paralysis consists in the loss of function by the anterior column alone, motor power being the only property destroyed: whence it was inferred that but a comparatively small part of the cord was disorganized. It may, therefore, be conceived that, in proportion as the spine sinks under the pressure of the superincumbent weight, and the angle at the seat of disease becomes more acute, the sound portions of the cord above and below the morbidly affected part of the anterior column, will approach more closely to one another: and that, in certain cases, their respective surfaces may coalesce and unite. In that manner the continuity of the column will be re-established, and its function restored. If this view be correct, it will follow that, should ankylosis of the vertebræ have taken place before the diseased surfaces of the bodies have come in contact, and when a permanent gap has been formed between them, there will be little chance of recovery. The prognosis is more favorable in children than in adults; which may be ascribed in considerable degree, at least, to the coalescence of the sound portions of the cord adverted to being more readily affected in the former than in the latter, owing to the greater flexibility of the spine in early life. The writer had lately under his care a boy, six years old, with angular deformity in the dorsal region. Within a period of two years, his lower limbs were twice completely paralyzed: the first time, for six months; the second, after an interval of eight months, for four. He recovered from the paraplegia, but afterwards died from the effects of extensive abscesses.

---

[1] "Contributions to the Pathology of the Spinal Cord," by William Budd, M.D. Med.-Chir. Trans., vol. xxii., p. 153.

The restoration of the power of the limbs, in some cases, is only partial. Certain groups of muscles continue paralyzed. This inequality in the condition of the muscles leads to particular forms of contractions and deformities, chiefly in the ankles and toes.

[The subject of the treatment of caries of the spine has awakened general interest within the last few years, and renewed attempts have been made to avoid the tedious treatment of absolute recumbency for a long period hitherto in vogue. For this latter to be effective it must be absolute, requiring not merely recumbency but the interdiction of all motion. The patient must be fixed either in a gouttière de Bonnet or bed-frame, so that the change of position necessary in nursing may be attended to without twisting the spine.

As a substitute for this, the method of treatment by fixation with plaster of Paris or other bandages or apparatus has deservedly attracted much attention.

No one who has watched a number of cases treated in this way can fail to acknowledge the great relief which is often afforded by a well-applied plaster-of-Paris jacket in suitable cases, but it is also true that they are not so universally beneficial as has been claimed.

It is also very doubtful whether suspension (as has been stated) pulls apart the diseased vertebræ on the principle of extension, or that this separation can be maintained by an appliance bearing down upon the pelvis for a base and pushing up upon the thorax as a surface for resistance. It has been demonstrated that in an advanced case of caries of the spine the bodies affected were not pulled apart by suspension,[1] and in early cases it is probable that the main effect of suspension is upon the physiological curves of the spine and not upon the pathological.

It is very exceptional for cases of caries of the spine to present themselves for treatment at a stage before the projection of a spinous process is evident. Such a projection results from extensive destruction of the anterior portion of the spinal column, a change which rarely takes place without such adhesions between the adjacent affected vertebræ as to limit motion.

It is however wrong to assume that the benefit derived from the plaster-of-Paris jacket is due entirely to its efficiency as a mode of fixation.

The more the spinal column is bent upon itself (with the concavity forward), as is the tendency in caries of the spine, the greater the pressure upon the diseased bodies from the superincumbent weight of the trunk and head. When the column is straight the pressure is diminished. If the column can be bent with the convexity forward there will be no pressure at the diseased point. The effect of suspension is of course to make a straight line of the curve; when the curve is pathological and not flexible this curve is not affected, but the normal part of the spine is brought to the vertical line, and on the application of a plaster-of-Paris jacket, prevented from bending forward.

A plaster-of-Paris jacket then, when properly applied, is a means of fixation in an improved position.

The flexible curves of the spine can be also corrected by placing the patient in a recumbent position. If the height of a person be measured when standing and also when lying flat upon a hard surface, it will be seen that the spinal column is apparently lengthened by this position. Plaster jackets can therefore be applied in this way, as has been recommended by Mr. Walker. (See also MINOR SURGERY.)

Before the application of the plaster bandages, the patient should be dressed in a close-fitting undershirt, and any bony projection should be protected from pressure by placing upon each side a thick pad; a folded towel should be placed on the abdomen, to be removed after the bandage has hardened, and thus allow space for enlargement of the abdomen from tympanites. This is not, however, always necessary.

[[1] Owen, Brit. Med. Journ., Feb. 28, 1880; see also Boston Med. and Surg. Journ., May 13, 1880.]

The bandages can be prepared by dusting plaster of Paris which has been but little exposed to the air upon any cloth with loose meshes. When the patient is placed in an apparatus for suspension the bandages are dipped in warm water (to which a little salt is added to quicken the "setting" of the plaster) and allowed to remain until the bubbles of air have ceased to rise. The bandages should be wound evenly about the trunk, and dry plaster from time to time be dusted on and rubbed in. If the bandages be made of the proper material, and enough plaster be rolled in the cloth, they will become hard very quickly, and the thin strips of steel sometimes incorporated in the jacket are not needed to give the bandage strength.

The amount of extension needed when suspension is employed varies according to the size of the patient and the seat and extent of the disease. The patient may be suspended either simply from the head by the use of a head sling, or with the addition of loops to pass under the axilla.

As soon as the jacket is sufficiently hard as to allow the patient to be lifted without bending or cracking, he should be placed flat upon a mattress until the appliance has become perfectly hard; the folded towel should be then removed and the bandage trimmed so as not to press on the axilla or thighs.

When instead of suspension, the recumbent position is used to straighten the spine, it is desirable that the plaster should not harden quickly, in order that sufficient time be given for the proper adjustment of the bandages; for this reason mucilage of acacia should be dissolved in the water to which the plaster of Paris is added, and strips of bandage passed through the plaster-of-Paris paste,[1] and laid one by one upon the bed, each bandage lapping the other. Three layers should be prepared in this way and the patient then placed upon it, and the strips of bandages placed around the trunk one after another. They should have been cut of sufficient length to encircle the trunk and allow a portion to lap. An efficient bandage can be applied in this way, but more care is required in preparation of the materials than when suspension is employed. Extension can be used while the patient is in a recumbent position, by the addition of a head sling and means of traction upon the lower limbs.[2]

The chief objection to the plaster jacket in treating a disease with as prolonged a course as caries of the spine, is that it is a fixed appliance and consequently unclean, and also that it is liable to cause chafing. To remedy these difficulties, as a substitute for plaster-of-Paris jackets, corsets of felt, leather, paper, and glue, have been used, moulded either to the figure of the patient or to a cast made from a plaster jacket, applied in the ordinary way.

These appliances can be readily removed, but they do not afford as thorough fixation as is given by a plaster jacket well applied.[1]

The object of treatment by means of steel apparatus is fixation. All apparatus designed to extend the spine by pressing upwards upon the axillæ and taking the base of support by a band encircling the pelvis are mechanically defective. The spinal column moves chiefly by bending forward, and to secure fixation this motion should be prevented. The simplest way to effect this is to straighten the spine by placing the patient in a recumbent position, and placing on the back an appliance consisting of two parallel strips of steel (without spring) bent to conform to the shape of the back, and being on each side of the spinous processes fastened at the bottom to a cross-piece which partly encircles the pelvis. An apron (with straps) placed upon the patient's abdomen and padded straps around the shoulders are buckled to the splint, and the spine is thus fixed.

To secure this fixation, however, great care must be exercised in the adjustment of straps, and fixing pads upon the steel uprights, in such a way that when the patient is standing the spinal column may not bend backward at that point, and thus increase the pressure on the diseased bodies. Such an appliance, if properly made and accurately adjusted, is readily worn by the patient, is easily removed, and is of great benefit, as has been abundantly proved by clinical experience. It however demands great care on the part of an attendant, and the constant supervision in the surgeon.

The object of this mode of treatment,

as originally proposed, was to transfer the superincumbent weight of the body from the bodies of the vertebræ to the transverse processes. That it would be mechanically possible to do this is probable, provided the affected vertebræ were not so far involved as to have become united by inflammatory changes. When, however, this has occurred, the effect of a brace is to fix in an improved position.

It is manifest that the mechanical problem required in fixation varies in different parts of the spinal column, and for this reason it is convenient to divide it into two parts, upper and lower. In the first it is necessary to provide some means for support or fixation of the head. In the second this is not necessary. The exact limit above which a head-support is needed is not exactly determined. According to some surgeons this is necessary in disease above the seventh dorsal; according to others the fourth dorsal.

The head-supports in use are: 1st. A bent rod fixed below in the appliance which encircles the trunk, and above bearing a sling which passes under the chin and occiput. 2d. A steel collar passing under the chin around the neck, and fastened behind to the apparatus fitted to the back. If this is properly adjusted, the weight of the head is partly supported by the rest under the chin, and all bowing forward is prevented.[1]

It may also be stated that the natural course of the disease varies according to its location. Paralysis is more common in disease of the upper portion. Treatment by surgical appliances is more effectual in the lower dorsal and upper lumbar region. Deformity is with more difficulty checked in the upper dorsal region.

It cannot be said that the methods of fixation have entirely done away with the necessity of recumbency in the treatment of caries of the spine. In some cases during certain stages it is best that the patient be kept absolutely upon the back. But it has been clearly shown that by means of surgical appliances recumbency need not be maintained (when it is required) during the whole course of treatment of the disease, and that the deformity resulting from the disease may be prevented from increasing or limited in its increase. Other cases progress to complete recovery under fixation by mechanical treatment, without any confinement or enforced recumbency.[2]]

Treatment of Spinal Disease.

The general treatment in spinal disease is founded on the same principles that guide us in hip-disease, scrofulous synovitis of the knee-joint, disease of the ankle, etc. The remedies are directed principally to sustain and strengthen a constitution originally weak and liable to be further debilitated by the effects of the disease. Hence, although it may be occasionally necessary to employ depleting measures for subduing temporary accessions of fever, or quelling short attacks of inflammation, they are adopted with reluctance, and the tonic system is otherwise pursued uninterruptedly.

Of local remedies, "rest" is deservedly placed at the head of the list. The object sought to be gained is twofold. First, by fixing the diseased vertebræ, we endeavor to prevent jarring and attrition between the rugged opposing surfaces of the carious bodies, and, by removing that source of irritation, to encourage the morbid action to cease. Secondly, by keeping the bones at perfect rest, we afford the parts the most favorable opportunity for becoming consolidated by ossific union.

The most effectual method of arresting motion between the diseased vertebræ, in aid of nature's efforts, is to place the patient in the recumbent position on his back; and to give him the greatest advantages whilst confined, it is desirable that he should be furnished with an invalid-bed, provided with conveniences for enabling him to lie upon it, day and night, without rising. If an ordinary couch be used, the patient will lie with greater security and comfort if the frame for the horsehair mattress, instead of being horizontal, be gently inclined downward from the top to where the hips come, and then be elevated (but to a slighter degree), with a double incline, for the knees to be bent over the angle. A hollow or socket for the reception of

Journal, London, 1879, ii., p. 891; Wood, "Double Extension," in Brit. Med. Journ., 1879, ii., 1023.]

the angular projection of the spine ought to be made in the mattress. Or a substitute may be contrived by filling an India-rubber pillow with sand, or suitable grain or seeds, and placing it under the patient's back, protected with blanket and sheet. In young persons, further security will be required, by enclosing the body in a stiff corset; and, perhaps, by strapping them down to the couch. It will add to the convenience if the bed-frame be portable, and capable of being easily transferred to the body of an invalid-carriage, or to a bench in the garden, with a view to the patient's getting fresh air.

It is an important duty of the surgeon to be peremptory in enforcing strict confinement in the recumbent position. He will find this task, of course, more difficult in children than in adults; and the principal cause is the freedom of the patient, in the majority of cases, from pain. Nevertheless, however moderate the symptoms with which the disease is ushered in may be at first, the incipient stage is a period during which a rigid observance of perfect rest ought to be insisted upon. And the time over which that care should extend ought not, even in the most favorable cases, including children, to be less than six or ten months. In patients approaching adolescence, the confinement must be longer.

If the case should proceed favorably, without pain in the back or abscesses coming forward, for the number of months specified above, the next practical question will be, concerning the propriety of liberating the patient from his long durance. That is equivalent to asking, how it may be ascertained that ankylosis has taken place; for it cannot be considered safe to allow the patient to get into the upright position till the bones have become strongly knit. Accordingly, in examining the angular projection, what has chiefly to be made out is, whether there be any motion between the affected bones; for if the part be perfectly stiff, it may be presumed that they are united. Atrophy of the muscles may assist in confirming the point. But it will not be prudent to rely on the solidity of the ankylosis altogether. The patient ought to be supplied with artificial supports. Space does not allow of a detailed description of the best kind of these instruments to be used in different cases; for, of course, they must vary, not only according to the situation of the disease, but the age of the patient. One general remark may be made, that the corsets are to be constructed much in the fashion of women's stays, so as to embrace the body above and below equally and generally; they ought also to be strengthened as much in front as practicable, to counteract the tendency to stoop forward. For giving them the proper stiffness, steel ribs are preferable to whalebone. In young, feeble children, whose bodies are extremely flexible, while their hips are too narrow for being used as a base of support, it may be found best to encase them in separate pieces of prepared leather, moulded to the body, and afterwards inserted in corsets; the lateral pieces or splints may be prolonged downward, to rest on the seat of the chair, and brought high enough to reach the armpits, so as to act as crutches while sitting.

Prone-couch.—A mode of reclining in the prone position, instead of on the back, has been much recommended. The method consists in making the patient lie upon his chest and abdomen, on an elevated frame, not unlike a desk, with an inclined board upon which his legs may hang: he is prevented from sliding by pegs at the top received into the arm-pits. The object of the position is, by fixing the upper part of the trunk, and allowing the hips and legs to glide down the incline, to keep the spine on the stretch, and so diminish the acuteness of the angle at the seat of disease. But such a design is opposed to the principles advocated above (see p. 308). It is evident that if the angular projection be diminished, the surfaces of the diseased bodies of the vertebræ, which ought to meet, will be kept apart, and ankylosis will be prevented. Moreover, as the patient cannot sleep, and cannot empty the bladder and rectum while confined on the apparatus, it will be necessary to move him frequently, to the great injury of the back. But it will, perhaps, be said, that although the employment of the prone-couch be not adapted to caries in its active stage, it may be advantageously used to improve the figure, when ankylosis has been effected. That desire on the part of patients, who have narrowly escaped death at the price of being deformed, to have their cure made absolutely perfect by getting rid of the hump on the back, may be natural; but it is scarcely necessary to say how utterly vain such hopes are.

Counter-irritants.—It is not long since, that in cases of angular deformity, issues were almost invariably ordered, on each side of the protuberant vertebræ, whether the patients were young and weak, or the disease acute or chronic, or there were abscesses or paraplegia. They had a debilitating effect, and were attended with much constitutional irritation. According to the practice of the present day, issues are reserved for subduing casual accessions of the morbid action, when the pain is great, or when there is a threatening of paraplegia. They effect all their good in a short time, so that it is not necessary to keep them open. Blisters give rise to so much general inconvenience that they are seldom had recourse to. Compound tincture of iodine, as a local application, has supplied us with an efficient substitute for these coarser remedies.

Disease of Atlas and Axis.

Disease affecting the two highest vertebræ of the spine has certain peculiarities which entitle it to separate consideration. The same cause which makes accidents to those bones more dangerous than elsewhere,[1] renders morbid action more perilous. The portion of spinal cord contained within the ring of the atlas is the most vital in the nervous system. Hence, whatever tends to weaken the joints in that part, exposes the patient to the hazard of sudden death, or of paraplegia including the whole body below the head.

Both atlas and axis, especially the former, differ from the other vertebræ in their anatomical structure. The atlas is deficient in the part that corresponds to a body; and there is no fibro-cartilage either between the axis, or the occipital bone and it: hence, as these structures are the proper seat of caries, it may be expected that the morbid process which attacks the two bones will differ from the ordinary disease of the spine.

The joints particularly subject to be affected are those between the atlas and axis. And a reason may be assigned for their being peculiarly prone to disease. The term "axis" implies that the vertebra so called is the centre of the rotatory movements of the head; and as the spokes in a carriage-wheel inserted into the axle act upon that central point with great lever power, so that when a break-down occurs it is the axle that gives way, a corresponding impulse is directed upon the pivot of the axis, by sudden violent rollings or twistings of the head. These shocks and sprains, often repeated, predispose the articulations, in a delicate patient, to disease.

The morbid action thus set up in the atlo-axial joints is similar in pathological character to what commonly occurs in the wrist, elbow, knee, etc. Proceeding generally in a chronic form, it gives rise to a gradual softening and spongy thickening of the synovial and fibrous tissues that connect the vertebræ; and subsequently to ulceration of the cartilages, and superficial corrosion of the bony structures. The disorganization will go on in most cases to an extreme degree without signs of abscess.

That which contributes principally, as intimated before, to the importance of disease in this locality, is the danger threatened to the spinal cord at its most vital part. Owing to the head being sustained on the atlas, and the ligaments which bind the latter and the axis ceasing to be able to retain them in position, the weight of the head causes the atlas to glide forward and downward upon the axis. This movement implies that not only are the articular surfaces separated from each other, but that the odontoid process of the axis is detached in an equal degree from the surface of the atlas which rolls upon it. Now, it is from this last-mentioned change that the risk to the spinal cord chiefly arises. The anterior arch of the atlas cannot be separated from the odontoid process, except by the stretching and elongation of the transverse ligament which embraces the neck of the process, and of the accessory restraining ligaments. Accordingly, if the weight directed on the atlas should be suddenly increased while this extension is in progress, and the ligaments are correspondingly weakened, the danger is imminent of the latter being ruptured. And should that event occur, there would be nothing to prevent the atlas, with the head as its freight, from sliding abruptly forward on the surface of the axis to its utmost reach. The consequence would be, that the portion of spinal cord contained within the ring of the atlas would be compressed by the posterior arch of that bone against the odontoid process in front, and be thoroughly crushed, and the patient's death would be instantaneous.

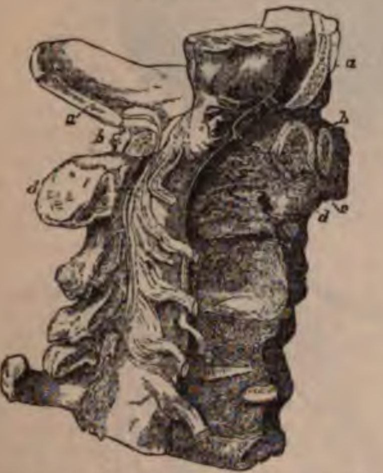
Case.—The patient, a butler, past the middle age, and corpulent, had for some time stiffness in the neck, with pains in the head and arms, supposed to be rheumatic. When seen by the writer, a large swelling extended from the upper third of the neck behind, to the highest part of the occiput, concealing the forms of all the bones which it covered, except the spinous process of the axis, which appeared unduly prominent. He could perform the nodding, but not the rotating motion, of the neck. The vertical axis of the head was advanced perceptibly too far forward, in comparison with the vertical axis of the neck; the effect apparently of the head having been transported to the front slightly beyond its proper plane in relation to the spine. The disease was seen to be atlo-axial, and he was removed to the hospital. Progressive paraplegia soon commenced, and it proceeded downwards; first one arm became weak and then paralyzed; shortly afterwards the other also became weak and paralyzed;

---

[1] See Injuries of the Back, Vol. I., p. 807.

and the lower extremities followed the same successive course. But before the legs were totally paralyzed he died, his death having been accelerated by a severe attack of bronchitis.

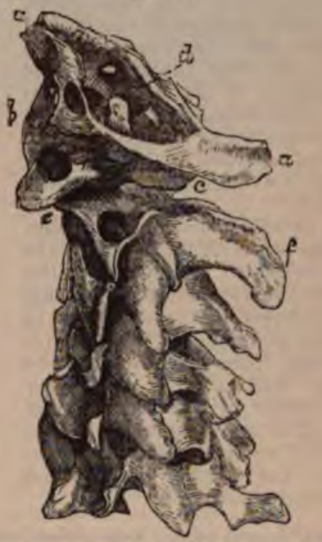
Fig. 686.



Atlo-axial disease. Figure from specimen in Middlesex Hospital Museum. *a, a.* Portion of occipital bone, in proper relations to atlas. *b, b.* Section of atlas. From destruction of the ligaments of the atlo-axial articulations, the atlas has slid forward, borne by the weight of the head, and has carried the odontoid process of the axis with it. *c.* Odontoid process of axis: loosened at its base by disease, it has been carried forward in connection with the atlas. *d, d.* Section of axis; its odontoid process detached: its articulations with the atlas, and with the body of third vertebra, and its body, all much diseased; the great projection backward of the spinous process in reference to the occiput and atlas, is a result of the gliding forward of the latter. Within its canal the spinal cord is seen bent at an obtuse angle; the consequence of the portion contained in the foramen magnum and atlas being carried forward, while that in the axis has been stationary.

But, happily, these cases are not always so formidable. In not a few, the transverse and restraining ligaments undergo extensive stretching of their fibres without being ruptured. They continue, therefore, to retain a hold of the atlas; and to keep a check upon it, as it glides forward upon the axis. Besides, the connecting structures in general surrounding the diseased vertebræ are agglutinated by deposition and induration of coagulable lymph, and the shifting movement proceeds slowly. Thus displacement may take place to an extraordinary degree. In many cases the atlas will be transported to the front to such a distance, that less than one-half will remain resting on the axis, the anterior part protruding unsupported beyond its level. The posterior arch of the atlas will then cease to be in relation or coaptation to that of the axis; it may be transported so far forward, that it will even bisect the vertebral canal into equal parts. Hence about a moiety of the area of the canal appropriated for holding the spinal cord and its membranes may be absolutely cut off. It might have been conjectured that a loss of substance, and alteration of figure so great as this description implies, would have been altogether incompatible with the cord retaining its functions. But experience shows that if the morbid action be chronic, and the dislocation take place slowly and gradually, the disease may run its course without paraplegia ensuing, and the patient will recover with deformity of the neck alone. Again, it is found that in those formidable cases in which para-

Fig. 687.

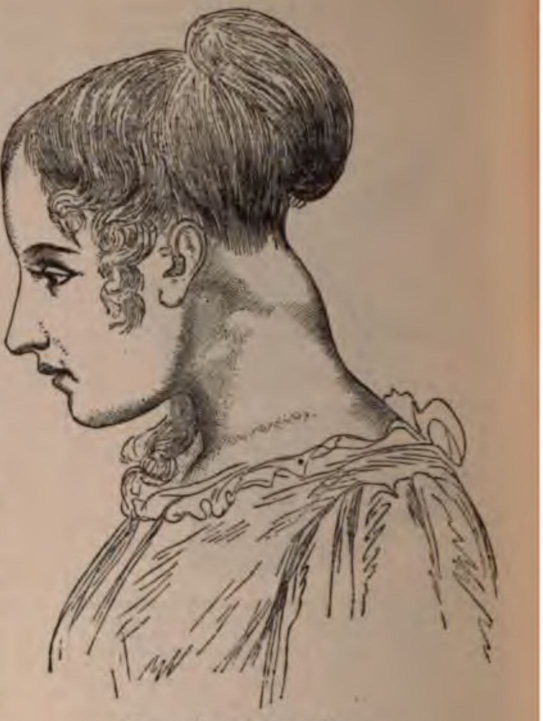


The specimen from which the figure was taken was removed from the body of a man found dead in the streets. There was fracture at the base of the skull, all round and at a short distance from the foramen magnum; the boundaries of the fracture being seen in the figure. *a, a.* Portion of occipital bone, insulated by the fracture. *b.* Anterior tubercle, on anterior arch of atlas. *c.* Posterior tubercle, on posterior arch of axis. *d.* Odontoid process of axis. Its situation corresponds nearly to the centre of the vertebral canal, at the level of the foramen magnum and atlas. *e.* Body of spinous process of axis. About three-fifths of the articulating surfaces of the atlas have been displaced forward on the corresponding surfaces of this bone, thereby accounting for the projection anteriorly of the front segment of the atlas. *f.* Spinous process of axis. The posterior segment of the ring of the atlas crosses the canal of the axis nearly in its middle. The distance between the posterior surface of the odontoid process, and anterior surface of the posterior arch of the atlas (the antero-posterior diameter of the vertebral canal), measures from a third to a quarter of an inch; that between the odontoid process and the anterior arch of the atlas, at the original sites of their articular facets, is five-eighths of an inch. The space between these points is traversed by an irregularly cylindrical beam of bone which unites the two surfaces: this new growth of bone is not visible in the drawing, but it had obviously been formed during the process of displacement of the atlas upon the axis, and attests the slow rate at which it had taken place. For a more detailed description of the specimen, accompanied with a drawing representing it in a different view, see Med.-Chir. Trans., vol. xxxi., p. 289.

plegia both of the upper and lower extremities has occurred, the patients may regain the power over their limbs, and be restored to perfect health; the spine, of course, remaining distorted. The phenomena are to be accounted for according to the pathological principle already adverted to (p. 317). The diminution in the substance and the disfigurement of the cord generally have been consequent on a slow process of interstitial change; and it has been seen that deviations from the normal size and shape, of the most surprisingly great kind, can be made in the spinal cord, as well as the brain, without sacrifice of their endowments, if wrought in that gradual manner.[1]

As in spinal disease generally, persons of scrofulous habit are more prone to be affected in the atlo-axial articulations. The last case observed by the writer was in a young woman, who, just after recovering from disease in these joints, had angular deformity from caries in the dorsal vertebræ. The most common age at which it commences is near puberty; but neither infants nor adults are exempt:

Fig. 688.



Disease of cervical vertebræ.

The girl, aged fifteen, from whom the drawing was taken (Fig. 688), had continued in her situation as a domestic servant, till three weeks before her admission into the hospital, at which time the neck was distorted as represented in the figure. The disease had apparently commenced four months previously, but it had caused so little pain or inconvenience that she had not been obliged to give up her work during its progress. She complained of pain darting from the swelling in the neck upward to the crown of the head, and downward over the shoulders, and along the arms. She had also slight incontinence of urine. The most prominent part of the swelling in the neck was formed by the spinous process of the axis; above which, and between it and the occiput, a distinct hollow could be felt. Chiefly by rest and counter-irritants she improved so much that in six weeks she was discharged. But three weeks afterwards she was readmitted on account of an aggravation of the former symptoms, and there being a weakness of the lower extremities, which caused them to sink under her when she attempted to walk. In a month she was sufficiently recovered to be sent to a convalescent hospital at the seaside. She subsequently called at various times at the hospital, to show that she had regained her strength completely. A cast from the neck is in the Museum of the Middlesex Hospital.

Symptoms.—A general swelling around the nape of the neck, attended with stiffness, and pain in motion, are the earliest indications of the disease. The patient will prefer the recumbent position to being erect; keeping his head sunk in a soft pillow. When upright he will steady his head by placing a hand on each side; and if asked to rotate it, he will stiffen his neck, and turn the whole body round. The nodding motions he will be able to perform. A sudden jolt, or a tap with the hand on the crown of the head, will give pain. As the swelling of the upper part of the neck may probably be mistaken at first for enlargement of the lymphatic glands, or for deeply-seated abscess arising from some other cause, the most certain mode of deciding the question as to the real nature of the disease, is to observe accurately the relative position of the spinous process of the axis to the occiput. Notwithstanding its large size, that process is not readily felt in the normal condition; it lies sunk in a hollow, arched over by the ligamentum nuchæ. But in atlo-axial disease the spinous process becomes distinct, not only to the touch, but to the eye. That change, however, is not consequent on the axis itself protruding; for this bone is stationary; the spinous process appears to project merely because the atlas, carrying the skull upon it, glides away to the front, thereby leaving it more exposed and defined. In conformity with this explanation, it will be perceived that the head droops, as it were, upon the neck; that the chin and face generally are advanced preternaturally forward in comparison with the throat, while the back of the head is deficient in rotundity and fulness in reference to the line of the spine. It may happen that one side of the atlas will move forward more than the other, when there will be added a little obliquity to the position of the head.

---

[1] In a specimen of consecutive dislocation of the atlas upon the axis described by Mr. Paget, the displacement exceeded what has been stated in the text. Fully two-thirds of the atlas must have been entirely thrown off the upper articulating surface of the axis. On measuring the part of the vertebral canal available for holding the spinal cord, it was found that the distance was only two lines from the odontoid process, and three lines, at the most, from the body of the axis to the posterior arch of the atlas (the normal measurements being from nine to eleven lines). In the neck of the odontoid process there was a deep indentation; which proved that the transverse ligament had retained its hold of the atlas to the last without being ruptured; and that the displacement had taken place slowly.—Med.-Chir. Trans., vol. xxxi., p. 285.

Prognosis.—Patients may pass through all stages of this complaint, till it ends in deformity and ankylosis, without any positive indication of the spinal cord having been affected. Yet the surgeon cannot fail to be in constant apprehension, and to watch every symptom narrowly. Pains darting upward to the back of the head, and simultaneously downward over the shoulders and clavicles, perhaps give the first alarm. The latter sensations are sometimes prolonged to the finger-ends, accompanied with slight muscular weakness. Such symptoms alone might be explained by supposing that the roots and trunks of the nerves given off from the cord in the neighborhood of the disease, had become affected by the process of displacement and morbid action external to the spine, without the medulla itself being involved. But prudence will not allow that view to be too much relied upon. Should there be added any symptom of the lower extremities becoming paralyzed —as a tendency to trip in walking, or a sense of pricking or of numbness in the feet—the conclusion will at once be drawn that the morbid action has penetrated to the medulla. In certain cases the paralysis of the upper and lower extremities will be but imperfectly pronounced; and it will pass off. In a single case seen by the writer, the muscles became affected with tonic spasm; the whole body was so rigid that on turning the patient in bed she rolled with the stiffness of a corpse having rigor mortis; that condition lasted for a month; it gave place gradually to ordinary paralysis, from which she eventually recovered. When the paraplegia is complete, the patient is in a singularly helpless state, being deprived of voluntary power and sensation both in the upper and lower extremities at once. Yet, notwithstanding the apparently hopeless condition of patients in these cases, experience proves that they frequently recover. The prognosis will be, of course, more favorable in young persons than in those above the middle period of life. With his colleague Dr. M. Crawford, the writer attended a man, whose age was forty-eight, for disease in the atlo-axial articulations; during six months his whole body, from the head to the toes, was paralyzed; yet he eventually recovered, with his neck merely stiff and distorted.[1]

Treatment.—In disease of the atlo-axial articulations, the utmost danger would be incurred if the patient fell forward on his head; in its stretched and attenuated condition the transverse ligament would readily give way, and the atlas would thus be free to slide forward and compress the spinal cord by its posterior arch. Special care is, therefore, required to preserve the head and neck of the patient in a state of perfect rest. Accordingly, constant uninterrupted confinement in the recumbent position is necessary. And the patient's head ought to be laid on cushions, which will prop it equally on every side. For that object, the India-rubber pillow, stuffed to a proper degree of firmness with grain, so that it may easily be pressed into a hollow which shall fit the back of the head and nape of the neck, is to be used. Or the sand-bags recommended by Mr. Hilton will be more easily procured. A band ought also to be passed over the forehead, from the sides of the pillow, to restrain motion. In the event of the patient being restless and liable to lift the head inadvertently, as during meals or sleep, it is a useful precaution to have a shield moulded, either in gutta-percha, or prepared leather, to the back of the neck; this ought to take in the shoulders below, and reach to the vertex above, so that it may be secured by bands both to the shoulders and head, to arrest movement.

---

[1] See a paper by Sir William Lawrence, "On Dislocations of the Uppermost Vertebræ of the Neck," in Med.-Chir. Trans., vol. viii. Also "Lectures on Pain and the Therapeutic Influence of Rest," by Mr. Hilton; Lecture V. A very remarkable case of disease of the superior cervical vertebræ, with intrusion of the atlas and axis, through the occipital bone, into the cranium, has been communicated by Dr. Lochee and Mr. C. H. Moore to the Lancet. See number for November 23, 1867. The preparation is in the Museum of the Middlesex Hospital.

Necrosis of atlas.—Before quitting the subject of diseases of the upper vertebræ, a rare affection of the atlas may be briefly noticed. This consists in necrosis and exfoliation of that part of the anterior arch of the bone which corresponds, in other vertebræ, to the body. The disease is connected with ulceration of the back of the pharynx; and it has been commonly observed in syphilitic patients. In some recorded cases, the whole thickness of the bone has come away, as shown by the articular surface of the odontoid process of the axis being visible. From the patient's surviving, it cannot be doubted that the insertions of the transverse ligament had been preserved entire; and that it had retained its hold of the process. A sloughing ulcer in the posterior fauces, with occasional attacks of difficult deglutition and breathing, have been the most prominent symptoms. When the fragment has been picked away, the sore has healed, and the patient recovered. It need scarcely be said, that a patient who has such a threatening disease, in a situation of so much danger to life, is in a critical condition while the dead portion of bone remains as a source of irritation, and that the greatest caution is demanded to protect him from sudden bending forward of the head.[1]

ORTHOPÆDIC SURGERY.

BY W. J. LITTLE, M.D.

Revised by E. H. BRADFORD, M.D.

[IT seems desirable that the word "orthopædic" should be spelt "orthopedic." Both ways are sanctioned by usage, as is also the practice of substituting e, as well as the diphthong æ, for the Greek αι. The term "orthopedic" is borrowed from the French, who coined the expression, spelling it without the diphthong, and there seems to be no good reason for disregarding the simpler way of writing the word.

Webbed Fingers.

All the fingers may be involved in this deformity, but usually only two fingers are joined.

In dividing the web, it is best to make an opening at the proximal end of the web, and allow it to heal before dividing the whole. This can be done by a galvano-cautery and the introduction of a foreign substance, such as a piece of silver wire or a piece of wood, until cicatrization has taken place, when the remaining portion can be divided. Sometimes it is feasible to perform a plastic operation, dissecting up the skin on the dorsal and palmar surface, dividing the web, and wrapping the flaps around each finger. This method, however, is not always successful.[2]

The other malformations of the fingers and toes may be classed as those caused by the presence of supernumerary digits; those with unnatural union of parts; those with a deficiency. These deformities are sometimes hereditary.]

Since the labors of Stromeyer, published in 1831, an important class of affections, denominated contractures and deformities, has deservedly much engaged the attention of the surgeon. Scarpa in 1803, Jörg, 1806, Rudolphi, 1823, Delpech, 1825, Dupuytren, and others, had, without much immediate fruit, endeavored to remove the obscurity in which this class of affections was involved. Their inquiries happily served to direct the researches of Stromeyer into a proper direction. The

Types of the different kinds of deformities of the hands and feet. (Bryant.)

term orthopædy has become generally used to signify the treatment of this class of affections.

The pathological nature of the affections relievable by surgical orthopædic treatment, often by division of tendons (tenotomy), is various. They consist mainly of alterations, in form and movement, of the articulations, especially of those belonging to the lower and upper extremities. These spring—

1. From accidental injuries of articulations; undue pressure and strain; inflammation of joints or contiguous parts, particularly those succeeded by suppuration and its consequences.
2. From derangement of the cerebro-spinal system, leading to paralysis or spasm and contraction.
3. From congenital influences, the varieties of club-foot, for example; malformations.

Orthopædic surgery comprehends, therefore, a multitude of abnormal forms of the muscular, ligamentous, and osseous systems, of which some are treated elsewhere in this work. On the pathology of deformities arising from diseases of the joints, the reader is referred to the essay on those diseases. Rachitic deformities are treated of in the essay on the SURGERY OF CHILDHOOD; spinal curvatures, in that on DISEASES OF THE JOINTS; strabismus, with DISEASES OF THE EYE; malformations, with the SURGERY OF CHILDHOOD; burn-contractures, under PLASTIC SURGERY. The affections which we have here to consider are principally those which can be remedied by division of tendons, by mechanical extension, or by both of these means combined.

Before proceeding with the description of the individual contractures relievable by tenotomy, it will be well to consider the circumstances which give rise to contraction and deformity, and to inquire into the condition of the muscles and tendons which renders their division necessary. It is now a well understood law of pathology, that if any part of the body, into the composition of which the muscles enter, be maintained in a state of absolute repose, or be habitually kept in one position, so that the origins and insertions of particular muscles are constantly approximated, whilst the points of origin and insertion of other muscles are consequently proportionately separated, a shortened, contracted condition of the first set of muscles, and an elongated, weakened state of the second set of muscles, are produced. This is illustrated by what occurs during a simple fracture or other injury of an extremity. If the elbow for example, be for any reason retained for a few weeks in the bent position, the muscles on the flexed side of the member become stiff and contracted, and are only gradually restored to their natural mobility by active and passive exercises and use, whilst the stretched-out and weakened extensor muscles recover but slowly their full power of extending the implicated articulation. The state of things just described is aggravated when inflammation, exudation, suppuration, loss of cutaneous or more deeply-situated tissues, and consequent adhesions and cicatrices, interpose pain and physical obstruction to the restoration of complete mobility. The greater duration of the disorder increases the probability that persevering or active remedial means will be required to obviate the shortening of one set of structures and the elongation and weakening of the opposite set. This shortening and contraction occur more rapidly during the earlier years of life.

The influence of paralysis in producing contracture varies according to the nature and extent of the seizure. A single muscle, as the sterno-cleido-mastoid, the tibialis anticus, or the external rectus of the eye, may be more or less completely paralyzed; and the antagonist sterno-mastoid, the gastrocnemius, the peronei, or the adductor oculi, may become contracted. Or several muscles habitually associated in their actions may lose their power of voluntary contraction, as the extensors of the wrist and fingers; and the opposing muscles also habitually associated in their actions, viz., the flexors of the wrist and fingers, become relatively shortened.

The demonstration of the precise amount and nature of the changes which occur in the central and peripheral parts of the nervous system, as far as apparent cause and morbid anatomy can teach us, and the determination of what particular functions of the muscles are primarily disturbed, belong to the special pathology of the nervous system, which need not here be entered upon. Few paralyses occur without some degree of contraction ensuing as a consequence, either directly from the impairment of the balance of muscular activity, or from forced repose or maintenance of the part in a particular position.

The induction by abrupt spasm of a more or less rigid, more or less permanently contracted state of a part, is obvious and easily intelligible; but the spasm which produces many persistent deformities is not always of that active, prompt, or tonic kind which is illustrated by certain cases of non-congenital wry-neck and club-foot, but is usually more slow and progressive, as seen in many children's cases of foot-deformity. The contraction in congenital club-foot and in the majority of congenital distortions can, we believe, be assigned only to a preternaturally excitable or spasmodic condition of the muscular fibres of the shortened muscles. In many cases, even when the shortened muscle has been set free by tenotomy, the morbidly excitable retractile disposition of the muscle often shows itself again after reunion of the divided part, and the cessation of employment of the mechanical or other means by which the affected muscle had been kept in an elongated state.

This contraction of certain muscles in congenital club-foot, which, for want of any other appropriate term, is designated spasmodic, is therefore very different from the active powerful retraction which occurs in certain comparatively sudden non-congenital cases, and in which the will of the individual is powerless to effect an improved condition of the limb. In congenital club-foot, and in analogous gradual non-congenital talipes in which paralysis does not exist, if the child is old enough to exercise volition, the affected muscles are to a certain extent subservient to the will, although volition is incapable of willing entire relaxation of the contracted muscles. Thus the contraction in this non-congenital non-paralytic talipes, the early stage of which we are able to watch, throws light on the congenital affection, the early stage of which is hidden in the uterus. In non-congenital cases of months' or years' duration, induced by cerebro-spinal affection or by reflex (?) disorder, the vital abnormal spastic contraction co-exists after a time with secondary structural change. We sometimes, however, before structural change has taken place, have an opportunity of witnessing that, although the patient walks with the heel, for example, much elevated, yet when he is seated, even with the knee extended, he can voluntarily bend the ankle,—contact of the sole with the ground exciting abnormal contraction. Further light is thrown upon the nature of the contraction in congenital club-foot by the observation that, during sleep, even in very young infants, the affected foot can be more readily straightened; also that, like as in certain cases of adult hemiplegia, when the child yawns and stretches out the limbs, the inversion of the foot often disappears. This observation would show, that whilst in the ordinary state of the infant's nascent volition the adductor muscles (the tibiales) overpower the abductors (the peronei) and invert the member, the act of yawning, with its complicated reflex activity of inspiratory muscles, and of associated muscles in the extremities, neutralizes the peculiar disturbance of muscular activity on which talipes varus depends.

It seems as if in congenital club-foot and analogous distortions a stimulus or irritant were present in the medulla spinalis, acting upon certain ganglionic cells there, which keeps the affected muscle in a state of tonic contraction, yet not sufficient to neutralize the stimulus of the will within the limits of movement permitted by the structural shortening of the member. Many non-congenital spastic contractions appear allied to the condition which prevails in some states of chorea, in which, when the will would permit or cause contraction or relaxation of a particular muscle, an involuntary influence excites contraction, interferes with, and frustrates the voluntary effort. In more intense spasmodic contractions the will is entirely overpowered before structural shortening supervenes to effect the same end.

[A consideration of the nature of the paralytic deformities involves a study of the paralytic disorders of childhood; a subject which has attracted a good deal of attention in the last decade, and which belongs properly to the department of medicine. A large number of these deformities are the result of the so-called infantile paralysis, or, more properly, myelitis of the anterior horns. This affection is characterized by a sudden onset of paralysis, affecting one or more limbs, and followed by progressive improvement for a while; so that a limb totally paralyzed may, in the course of a few months, regain power either entirely, or with the exception of certain muscles. Those muscles or groups of muscles which remain paralyzed after the first year following the initial onset are to be regarded as permanently useless. (Charcot, Volkmann.) These groups are usually those on the anterior surface of the thigh and leg, or the parts which are kept on the stretch when the limb is flexed, a position usually assumed when the child is unable to stand or unwilling to be recumbent all the time. The muscles on the posterior surfaces are those more frequently spared or less injured. Hence the theory has been suggested that a cause of this permanent paralysis, or rather such of it as is not due to the central lesion of the cord, is the fact that the weakened muscles have been overstretched, while the others which regain power have been protected from strain and subsequent fatty or fibrous degeneration. The deformities are not, therefore, according to certain writers, due to a spasm of certain muscles, but to the position the limbs assumed; a position which becomes permanent as the protected muscles develop and the stretched muscles become enfeebled.[1]

Of the "spastic distortions," a certain number are those which are due to cerebral palsies, and some come properly under the head of Spastic Spinal Paralysis.[2] It is probably this class of affections which Mr. Adams mentions as deformities with rigid muscles, and which are interesting to the surgeon chiefly from the fact that they are not as a rule much benefited by treatment.

The surgical treatment of ordinary infantile paralysis and the resulting deformities must be regarded as unsatisfactory also, if it be expected that by surgical interference a cure can be effected; much benefit can, however, be afforded by correcting the deformities and by furnishing proper supports. The deformities can be corrected without the employment of tenotomy in a majority of cases; there seems, however, to be little disadvantage from its use. The supports required vary in each case, and much care is required in the proper selection of them. The object of apparatus after the deformity is corrected is to prevent the enfeebled limb from giving way when the weight of the body is thrown upon it. In paralyses of the muscles of the leg, the inclination of the foot is toward a position of varus or valgus, with or without the dropping of the forepart of the foot. This deformity is to be treated as those from ordinary congenital club-foot, except that support will be required after the foot has been brought into place. When the extensor muscles of the leg are affected, it is necessary to prevent the knee from falling forward, or the patient is unable to stand. This can be accomplished without difficulty by means of apparatus devised for the purpose, and locomotion becomes possible. In paralyses of the upper extremity little is to be gained by mechanical treatment.]

To resume, then: clinical observation of non-congenital deformities, springing from derangement of the nervous system, teaches that there are several modes in which they are produced. These modes are as follows:—

1. Paralytic distortions.
    - *a.* Certain muscles only being partially or wholly paralyzed, their antagonists slowly contract the dependent articulation.
    - *b.* The muscles of the part in general being partially or wholly paralyzed, the contractility of the greater mass, as of the flexors in the extremities, slowly contracts the dependent articulation.
2. Spastic distortions.
    - *a.* The contraction is severe and prompt, the will being quite overpowered or absent.
    - *b.* The contraction is gradual, as in the majority of (non-paralytic) cases of non-congenital talipes, the will not being wholly overcome (those reputed from teething, for example), but restricted by the morbid innervation, and in time by structural shortening.

[[2] Tabes Dorsalis Spasmodique, Charcot; described by Erb, Allg. Med. Central. Zeitung, Nov. 21, 1877, and others.]

c. The contraction is gradual but severe, as in the deformities which sometimes accompany imbecility in children. It is probable, in this form, that the contraction is intensified by the co-existence of an enfeebled condition of general volition, a general inertia favoring repose of members, and a greater amount of structural change.

Secondary changes.—From whichever of the above causes a constantly contracted state of an articulation or limb may have proceeded, the state of things consisting of the inability of the individual to put the part, by the action of the will, through all its proper movements is called a deformity. But if the patient by means of his own hands, or if the surgeon, can overcome the contraction, and put the affected part through its proper movements, no deformity is in reality seen to exist. Positive deformity may early exist, when original disease of the joint has, besides producing contraction, ended in more or less considerable alteration in form and structure of the articulation. But almost equally serious (secondary) deformity may ensue through the influence of the now ill-regulated muscles of the joint, especially when these act upon tissues impaired by disease—the production of sub-luxation for example. In the lower extremity, the effect of the weight of the body being borne upon the member in improper directions is a very important cause of secondary deformity, adding greatly to the obstacles to restoration. Thus a not severe case of congenital club-foot, remediable in point of form in a few weeks before walking has commenced, may subsequently require treatment of months or of years; or, from the deteriorating cause above mentioned, be rendered irremediable.

We may now pass to the consideration of the means employed in Orthopædic Surgery for the rectification of deformities. This department of practice avails itself of much that is common with general medicine and surgery.[1] Special orthopædic means are, the relieving of the shortened parts by the employment of mechanical instruments, or mechanical power exerted by the hands of the surgeon or assistants, sometimes with the aid of the benumbing influence of chloroform, and by division of one or more of the contracted muscles, tendons, and fasciæ.

Tenotomy, myotomy.—In this operation the necessary relaxation of muscular resistance and of accompanying structural shortening is effected by severing the muscle at its tendinous portion. The principles laid down by Delpech for the performance of this operation are followed in the present day. It is remarkable that Delpech never carried out his own principles.[1] The discovery and application of subcutaneous tenotomy belong to Stromeyer. Many alterations in the mode of applying these principles have been made since the original labors of Delpech and Stromeyer. Various knives for severing tendons (tenotomes), and a great variety of mechanical extension-apparatus, have been devised. In this place only the means in most general use in this country will be described.

In describing the several distortions in the treatment of which tenotomy and mechanical treatment may singly or conjointly be requisite, no nosological order will be adopted. We will commence with congenital club-foot (talipes varus congenitus), because it is one of the most common distortions which the surgeon has to treat, and because it has formed the basis of extensive pathological and therapeutical research. The consideration of the scientific treatment of club-foot will, therefore, best illustrate the principles upon which the management of all other distortions should be conducted.

No other deformity exhibits in a greater degree the incidents of orthopædic experience.

Congenital Club-foot (Talipes varus congenitus).

It is undesirable to attempt here even a sketch of the history of the acquaintance of our profession with club-foot. It will suffice to mention that the subject engaged the attention of Hippocrates amongst the ancients, and of Scarpa amongst the moderns. But it was not until the genius and energy of Stromeyer were combined with a sound acquaintance with the principles and practice of modern surgery, that the complete treatment of severe club-foot became possible.

Anatomy of club-foot.—Former opinions on the anatomy of club-foot may be advantageously passed over.[2] In 1837, and subsequently, the author laid down the essential characters of the anatomy of club-foot.[3] The subject has since been carefully and successfully studied by Mr. William Adams.[1] The general result of observations of this matter is the confirmation of the opinions emitted by the author in 1837 and 1839,[2] that club-foot consists of a threefold alteration of the form and position of the foot, the heel being elevated, the toes turned in, and the internal margin of the foot raised from the ground, owing to abnormal action and shortening of the principal, if not of all the muscles of the inner and back part of the leg. Perhaps, also, at least in the severer forms, those in which the sole is much contracted, the plantar muscles participate in the primary affection. The ligaments, fasciæ, and integuments on the contracted side of the member are also shortened, whilst the similar tissues on the opposite side are elongated and weakened. These passive tissues follow the fortunes of the active organs—the muscles, on which they are in the main dependent, and become thus secondarily affected. The bones, before and after ossification, suffer in proportion to the intensity of the muscular contraction, and probably in proportion to the earliness of the period of uterine existence at which the distortion commenced; and especially in proportion to the period that elapses after birth, during which the passive osseous structures remain at the mercy of the active muscular agents. The bones further suffer as age advances, by bearing the weight of the body in an improper direction.

[3] Dissertatio inauguralis de Talipede Varo, Berlin, 1837.

The departure from the normal form and relation of bones may be divided into—

1. Primary.
   - *a.* The changes especially affecting the tibio-tarsal joint.
   - *b.* The change of relation of the anterior bones of the tarsus, as regards the astragalus and os calcis.
2. Secondary, or those induced after birth, by spontaneous aggravation of the deformity, and by pressure upon the parts through walking in an improper manner.

[Mr. William Adams has clearly demonstrated that in club-foot, even in infantile and fœtal specimens, a decided malformation of the astragalus takes place. He finds that the fœtal astragalus presents all the essential changes in form observable in the adult, and hence all the changes found in the bones in the dissection of well-developed club-foot are not the result of "spontaneous aggravation of the deformity." He therefore finds himself unable to confirm the opinion of Dr. Little in regard to the "immaterial changes which the bones undergo previously to the use of the part."[1]

Mr. Adams found that the neck of the astragalus, instead of being continued directly forward as in the healthy bone, inclines abruptly inward, forming an obtuse angle with the body of the bone. The articular head of the astragalus has an antero-lateral aspect. In severe cases the articular surface is divided into two facets separated by a ridge; the one articulates with the displaced navicular bone, and the other is uncovered. The other bones of the tarsus, according to Mr. Adams's dissections of fœtal distortions, are not altered materially in form, although their position is abnormal, and nothing unusual is found in the size or position of the malleolus.

Kocher, however, found, in a dissection of a specimen of congenital talipes varus in an infant, alteration in form of all the bones and joints of the tarsus.[2]]

The anatomical changes of bones in varus of practical moment are due to the state of extension of the os calcis, taking with it the astragalus, through which the posterior extremity of the os calcis is more or less closely approximated to the posterior surface of the ankle-joint; and the anterior portions of the articulating surfaces of the trochlea of the astragalus are projected from the ankle-joint in front. Owing also to the forced inversion of the entire foot, the external malleolus is thrown backwards towards the posterior tuberosity of the os calcis, and the anterior extremity of the astragalus slightly inclines towards the inner margin of the foot. The forced elevation of the posterior part of the foot (calcaneum and astragalus) is common to talipes varus and to talipes equinus; but the characteristic peculiarity of varus is the displacement of the remaining bones of the tarsus inwardly to the extent that the navicular bone quits the astragalus, often touching the internal malleolus, with which it frequently acquires a new articulating surface. The cuneiform and cuboid bones accompany the navicular. Moreover, in severe cases the cuneiform, cuboid, and metatarsals, with the phalanges, are drawn backwards, limiting the space of the plantar region.

The changes of bones induced by im-

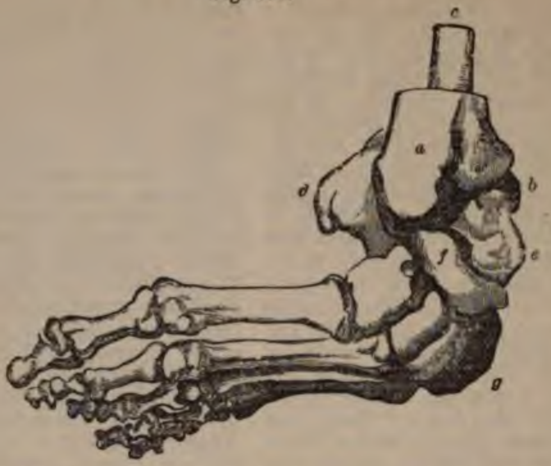
[2] Treatise on Club-foot and analogous Distortions, London, 1839. A large number of treatises on club-foot have appeared since 1837, few of which contain any fundamental researches into the anatomy of varus.

[[1] Club-foot, Wm. Adams, 2d edition, p. 149.]

[[2] Deutsche Zeitschrift f. Chir., 9th Bd., 3d and 4th Heft, p. 329.]

Fig. 690.



Severe adult congenital Varus, viewed from the front and outer side; *a*, the tibia, cut down in order to show the relatively posterior situation of the fibula; *b*, the external malleolus; *c*, the fibula; *d*, the posterior extremity of the os calcis, drawn abnormally inwards; *e*, the astragalus, unduly prominent on the dorsum of the foot; *f*, the navicular bone in contact with the internal malleolus; *g*, the cuboid, its proper superior surface applied to the ground.

proper walking, improper pressure and bearing against the ground, by which also sometimes inflammation and ulceration of soft parts are occasioned, do not properly belong to simple uncomplicated club-foot. Only when these injuries are considerable do they affect the results of treatment.

The shortening of the ligaments, fasciæ, and integuments on the posterior and internal aspects of the member may be observed when, before or after operation, attempts are made with the hand to rectify the deformity. In severe cases, much resistance to cure is offered by the posterior ligament of the ankle, the deltoid, the calcaneo-scaphoid, the superficial and deep plantar ligaments. The share of resistance offered by the deltoid, for example, is well shown when dissecting severe infantile varus. After removal of the superficial textures (integuments, fasciæ, muscles, and tendons), much amelioration of shape results; but the ligaments of the ankle being intact, it is observed that the foot still retains a varus form. But when the deltoid ligament is severed, and the navicular bone is liberated, a marked facility of replacement is evinced.

The general direction of the structures involved in the distortion is much altered. Thus, the leg-bones are inwardly rotated from the knee-joint. The surgeon should not expect to find the tendons occupying their normal relations. Those passing over the front of the ankle-joint are deflected inwardly, whilst the posterior tibial tendon appears more deeply situated, owing to the incurvation, and to the backward dragging, and elevation of the anterior part of the foot.

[The dynamic theory of the causation of club-foot, is one which latterly has been subjected to a good deal of criticism, chiefly by German authorities.[1]

It may be said that the greater weight of German authority on this subject is in favor of the theory that ordinary congenital club-foot is due to abnormal intra-uterine pressure occurring during the earlier months of pregnancy. The arguments to support this view are based chiefly upon the fact that dissections of congenital club-foot give evidence of a change of shape in the bones of the tarsus which it is deemed are more likely to occur from unusual pressure than from muscular action of undeveloped muscles. Kocher believes that club-foot is the result of external pressure affecting the foot as a whole, and not a primary change in a single bone. He found after dissection that all the joints and bones of the tarsus of congenital club-foot suffer alteration in form. This external pressure is supposed to begin in the first half of pregnancy before the formation of a joint.

It is undoubtedly true that club-foot often coexists with derangement of the nervous centres, as in acephalous fœtuses, etc., but it does not follow that the latter must be regarded as a cause of the former, and not the result of a common cause. That certain distortions of the feet may arise from a spastic condition of certain muscles is beyond question, but it cannot be regarded as so evident that the ordinary talipes varus originating early in gestation, when it may be supposed that nervous derangements would be of little influence, must necessarily be due to muscular spasm. It is certainly as easy to explain the fact of unilateral deformity on the theory of pressure as upon that of central nervous derangement. And while it is true that amniotic fluid is normally in abundance during the early months of gestation, it is not known to be always so. Acquired club-foot resembles congenital club-foot in a degree, but acquired deformity or any deformity resulting from muscular spasm bears little similarity to severe congenital talipes varus in a limb not used. It is also probable that acquired club-foot following infantile paralysis is not the result of muscular spasm and the direct effect of a disturbance of the muscular balance, but rather to the action of gravity, unusual posture, or abnormally distributed weight upon an enfeebled limb.[1] It is moreover difficult to explain fully on the supposition of the dynamic theory the distortion of the whole limb seen in congenital talipes varus of a severe type (p. 334).

---

[1] [Kocher, Deutsche Zeitschrift f. Chir., 9th Bd., 3d and 4th Heft, p. 329.]

Neither theory is satisfactory, and for the solution of the question we must await future investigations.]

Etiology of congenital club-foot.—The primary cause of talipes varus congenitus has been already touched upon, p. 328. It consists in an alteration of the dynamic properties of certain muscles, apt to be accompanied or followed by structural shortening,[2] and by fibrous and adipose degeneration of them.[3] Until the researches of Rudolphi, it was held that club-foot, as well as other distortions and malformations, were the consequence of some "occult influences," lusus naturæ, maternal imagination, and intra-uterine pressure. An occasional effort is made to revive the last of these theories, that of intra-uterine pressure. It has been elsewhere shown[4] that accidental mechanical causes do sometimes act upon the fœtus, giving rise to easily recognizable conditions, *e. g.*, fissures, clefts, intra-uterine fractures, amputations of members from constriction by abnormal bands or by the umbilical cord; and sometimes the co-operation of pressure by the uterine walls and pelvic bones may be surmised.

The arguments in favor of the belief that ordinary congenital club-foot is caused by some derangement of the cerebro-spinal centres and dependent nerves, as opposed to the theory of its dependence upon pressure of the walls of the uterus, may be thus stated:—

Club-foot often co-exists with evident derangement of the nervous centres, as in acephalous, hemicephalous, and spina bifida subjects.

Club-foot occasionally co-exists with an analogous distortion of the upper extremity, club-hand, in which the muscles contracted are the anatomical analogues of the parts contracted in the lower limbs. Now if it be admitted that the external configuration of double club-foot may suggest to the unphysiological and unpathological observer the idea of one of the feet having overlapped the other in such manner that the uterus, *supposing* the liquor amnii to be deficient, has compressed the two feet into the form in which we see them, this explanation does not apply to the club-hands, which bear no such form as can be reasonably attributed to pressure of the uterine walls. Moreover, club-foot often exists in one foot only, and the uterine-pressure theory does not explain why one foot escapes. This theory is still less applicable to the highest grade of club-foot, in which the great toe is more approximated to the inside of the leg than pressure of the uterus will explain; whilst the opinion of undue (spastic) action of the muscles before the articulating ends of bones can restrict their action, affords an intelligible explanation.

Club-foot is met with in fœtuses before the fourth or fifth month of gestation, at which period the liquor amnii is relatively so large as to exclude the idea of uterine pressure consequent upon *supposed* deficiency of that fluid.

Congenital club-foot can often be traced to hereditary influence, sometimes on the father's side, sometimes on the mother's side. We have traced it on the paternal side even through four generations, the male infant, the father, the grandfather, and the great-grandfather. If it can be plausibly maintained that club-foot is due to the influence of uterine pressure, deficiency of liquor amnii, pressure of pelvic bones, and its repetition through successive generations, this influence could only be propagated through the female side. We cannot admit uterine influence in hereditary propagation of varus through an uninterrupted succession of male parents.

A comparison of club-foot with the distortions which occur after birth, unmistakably from diseases of the nervous system, tends to prove that congenital and non-congenital club-foot spring from analogous causes. Distortion after birth, from altered innervation of muscles, is more common in the lower extremities, and especially in the feet, than in any other part of the frame. Club-foot is also the most common distortion before birth. After birth, talipes varus, in consequence

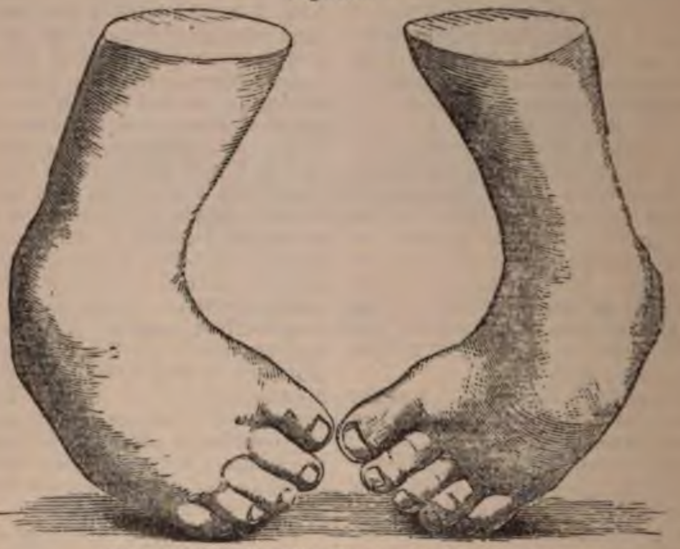
[4] On Deformities of the Human Frame, pp. 256-314.

of cerebro-spinal affection, is more common than talipes valgus; before birth also, varus is more common than valgus. After birth, foot-deformity, from disease of the nervous system, attains often a higher grade on the left than on the right side. This is equally the case with congenital club-foot. Some other agency than accidental uterine or pelvic pressure is required to account for these analogies; they cannot be regarded as mere coincidences.

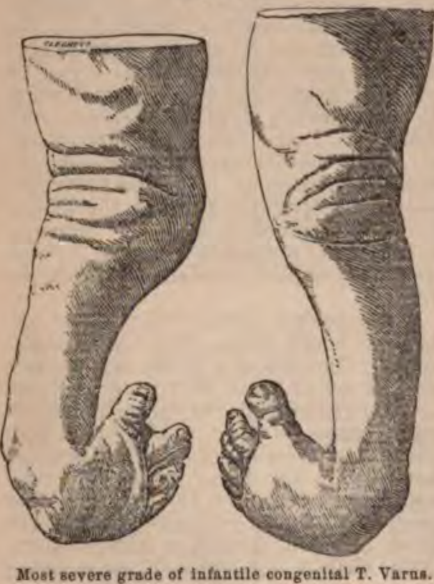
Grades of congenital talipes varus.—It is convenient for practical purposes to divide congenital club-foot into three degrees of severity: the slightest, that in which the position of the front of the foot when inverted is such that the angle formed by it with the inside of the leg is greater than a right angle, and in which the contraction is so moderate that the toes can easily be brought temporarily by the hand of the surgeon into a straight line with the leg, and the heel be depressed to the natural position. The second class includes those in which the inversion of the foot and elevation of the heel appear the same or little greater than in those of the first class, but in which no reasonable effort of the surgeon's hands will temporarily extinguish the contraction and deformity. The third class comprises those in which the contraction of soft parts and displacement of hard parts reaches the highest degree, so that the inner margin of the foot is situated at an acute angle with the inside of the leg, sometimes is even almost in contact with it.

Fig. 691.



Congenital infantile Talipes Varus, of medium severity.

Fig. 692.



Most severe grade of infantile congenital T. Varus.

Cases of the first and second grades may be respectively converted into the second and third grades by delay in the application of remedies, and by the effects of improper locomotion.

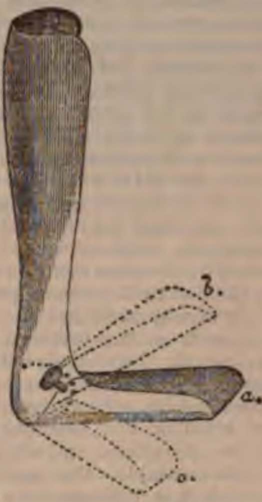
[Scarpa, believing that in club-foot no deformity of the astragalus was to be found, except such as would be developed by the persistence of the deformity, based his idea of treatment upon this fact; and tenotomy was necessarily regarded as the chief agent in effecting a cure. The introduction of tenotomy was certainly a great step in advance in the treatment of club-foot, but its general use has given rise to a belief that proper section of the tendons with means to restore the proper balance of the muscles sufficed to cure club-foot. This has led to numerous failures, or but partial successes, and even to a wholesale denunciation of tenotomy.

Club-foot is now to be regarded as a distortion brought about by a change in almost all the tissues around the mediotarsal joint, and a change in the shape of the astragalus. Treatment consists not only in overcoming the shortening of the muscles, ligaments, fasciæ, etc., on the contracted side of the member, bringing the bones into their proper position, and strengthening the weakened muscles—but also in preventing relapse until the shape of the astragalus and its relation to the scaphoid becomes sufficiently normal to make a relapse impossible. This is clearly shown by a dissection of Mr. Adams of the foot of a child six years old. Talipes equino-varus had been successfully treated by Mr. Lonsdale, and the foot had been brought into nearly a normal position. On examination after death it was found that marked obliquity of the neck of the astragalus still remained. As the growth of bone is quite rapid in the first year of life, its treatment should be begun as early as possible. There can be no question of the advantages of tenotomy, and the objections urged against its use[1] do not seem well grounded; but this procedure must be regarded as a means to aid in placing the foot in a normal position, but not as alone capable of a cure.]

Treatment.—The indications are to overcome the shortening of the muscles, ligaments, fasciæ, and integuments on the contracted side of the member; to direct the bones into their proper position; to educate the patient's voluntary use of the parts; to give strength to the muscles and ligaments on the elongated side of the member, and to combat the tendency to relapse.

A few slight cases may from the day of birth almost be relinquished to the rubbings and manipulations of the nurse; some require to be lightly bandaged on a strip of tin or firmer metal, bent to a right angle, and properly padded; others require support not only beneath the sole, and against the back of the leg, as when a simple bent strip of metal is employed, but need lateral support or pressure against the internal margin of the foot, as by the application of a tin splint devised by the author (see fig. 693). In the use of this and similar contrivances to be found at the different surgical instrument-makers', the essential point consists in applying the smallest amount of pressure compatible with maintaining the apparatus on the limb, not endeavoring at once either to force the part straight or even to make the tender infantile foot accurately fit the apparatus, but rather, if the apparatus selected admits of adaptation, to adjust it to the foot in a somewhat improved position. Practitioners unacquainted with the details of management of these cases are surprised to discover how small an amount of pressure suffices in young infants rapidly to improve the form and flexibility. The splint should daily once, or oftener, be removed to ascertain that undue pressure has not been used, to replace it when loosened by the movements of the child, and to improve the position as often as practicable. No unnecessary loss of time should be permitted during this process, as at first the foot rapidly relapses to its most distorted condition.

Fig. 693.



[Mr. Barwell has advocated a system of the treatment of club-foot by means of artificial "rubber muscles," with the object of supplying the strength of the weakened muscles by rubber cords which are arranged as far as possible to exert traction in the direction of the normal muscles. The upper attachment of the "rubber muscle" is that given by securing it to a plate which is fastened to the limb by adhesive plaster, the lower attachment is to the foot, to which adhesive plaster is applied.[1] It is perfectly true that congenital club-foot can be corrected in this way without having recourse to tenotomy, and it is also true that the contraction can be overcome in an uncomplicated case of club-foot as thoroughly in this way as by tenotomy. Tenotomy, however, has no especial disadvantages which have been satisfactorily demonstrated.]

---

[1] Barwell on Club-foot.]

[1] Barwell, Club-foot; Sayre, Club-foot.]

If at the expiration of the fourth week distinct contraction of the tendons remain perceptible in spite of assiduous efforts to overcome the deformity by manipulations, frictions, and steady but gentle employment of splint and bandage, or if benefit proportionate to the attention bestowed be not realized, or if the case unequivocally belongs to the second or third degrees of varus, the aid of tenotomy will be required to effect restoration. If the surgeon should entertain doubt whether the time for operation have arrived, he may be determined by the observation whether, on holding the foot in the normal position, it springs vigorously back into the abnormal one as soon as the pressure of the hands is removed. In unequivocal cases of the second and third degrees he may, in most cases, decide affirmatively at the moment of birth on the absolute necessity of future operation; and when operation is indispensable, the earlier the period at which it is performed the better. Mr. Stromeyer Little has operated within twenty-four hours after birth with rapid and permanent success. Our practice of late years has been to operate as soon as convenient during "the month." The surgeon, when deciding on the necessity of operation, must not be guided solely by the external configuration, but by the amount of firm resistance opposed to restoration, by the depth of the furrows existing in the sole and behind and above the heel, and by the degree of tension of the integuments about the internal malleolus. The deep clefts or furrows in question denote intensity of contraction of muscles, and closer adhesion than usual of integuments and fasciæ to the subjacent soft structures and bones. They probably denote also that the deformity dates from an early period of uterine existence. Even atrophy, the usual concomitant of contractions of long duration, is already present in severe club-foot of new-born children, and is a measure of the length of time the muscles have been contracted and exposed to structural shortening and possible degeneration.

Nature of the operation.—The essential character of congenital talipes varus being a state of abnormal elevation of the heel, and inversion of the front part of the foot by undue muscular contraction, the operative interference required consists of the division of the tendons of those muscles which are mainly, if not exclusively, concerned in the production of the deformity, viz. the tendons of the anterior and posterior tibials, and the tendo Achillis. In average cases these three tendons may be divided at one operation. In severer cases the operation should invariably be divided into two parts, the first consisting of the section of those structures which contribute to the inversion—the tibiales tendons; and where the sole is much contracted with a strong prominent band felt at the inner edge of the plantar fascia, that band may be included in this portion of the operation. The division of the plantar textures and elongation of the sole may in severe cases advantageously precede the section of other structures. The tendo Achillis may in such cases be severed in three or four weeks; in adults, two or four months later; the inversion having, in the interval, been overcome. The value of this proceeding, first recommended by the author,[1] consists in the os calcis, when the tendo Achillis is left intact, offering a *point d'appui*, or resisting point, from which the surgeon, during the mechanical after-treatment, is enabled to stretch out and unfold the contracted involuted sole. If this division of the operation into two or three parts is not observed in bad cases, incomplete recovery may result, the sole remain contracted, and the individual walk unduly on the heel, the range of motion of the point of the foot being deficient—in short, a secondary talipes calcaneus be produced. This secondary deformity is always overcome with difficulty, sometimes it is irremovable.

In a few adolescent and neglected adult cases of congenital equinus and varus, even the peronei may need division, these muscles having become, from protracted duration of the deformity, tensely contracted and considerably shortened.

The following is the mode of dividing some of these tendons, and the instruments which we have introduced as the most appropriate for the purpose. The operation is more quickly and more conveniently done by taking the three tendons in the following order, viz., the posterior tibial, the anterior tibial, and the tendo Achillis. Section of the posterior tibial is best performed by placing the child on a table of convenient height, on its back, inclined towards the limb to be operated on. This should be thoroughly rotated outwardly, resting upon its outer side, whilst a competent nurse holds the child's hands and the opposite leg out of the way of the surgeon. An assistant, having a small dossil of lint, a bandage, and the necessary knives within reach, takes his place by the side of the patient, and holds the thigh and knee of the limb to be operated on with one hand, being prepared with the other to hold firmly or adduct the foot, as may be required. The operator, when about to sever the left posterior tibial, seats himself in front, takes the foot in his left hand, and endeavors to feel the slight prominence of the posterior tibial tendon with the left thumb; during the time he either abducts the foot with the right, to put the tendon on the stretch, or takes advantage, during the spontaneous movements of the infant, to observe where the tendon is drawn into palpable relief.

---

[1] Lancet, May 25, 1839.

When, however, the surgeon cannot feel the tendon, it is practically quite sufficient to make out the inner edge of the tibia, about a finger's breadth above the lower end of the inner malleolus; or should there be any difficulty in defining this ridge of bone in consequence of the fatness of the limb, the careful insertion of the knife *exactly midway between the anterior and posterior borders of the leg*, on its inner aspect, will be an exact guide to the position of the tendon, not forgetting, as anatomy teaches us, that an incision made a little in front of this line might wound the internal saphena vein and nerve; and if made behind it, would run the risk of dividing the flexor communis digitorum instead of the tibialis posticus; or the knife might even pass posterior to the former tendon, and, if carried deep enough, might wound the artery and nerve without touching any tendon whatever.

Having thus determined the situation of the posterior tibial by one or all of these methods, a sharp-pointed knife is passed through the skin at about a finger's breadth above the inner malleolus, according to the age of the child. It must be made to penetrate steadily down, *perpendicularly to the surface*, to a depth varying from a quarter to half an inch. In doing this, it is necessary to be quite sure of sufficiently opening the fascia covering the posterior tibial and common flexor tendons; otherwise, when the probe-pointed knife is passed in (as will be described in the next stage of the operation), it may either hitch against this dense unyielding structure, or glide over its surface behind the deep layer of muscles, instead of passing through the opening in front of them.

In order, therefore, to accomplish the *free division* of this fascia of the leg close to its insertion into the edge of the tibia, and likewise the proper sheath of the posterior tibial tendon beneath, the sharp-pointed knife should be passed to the depth above recommended; the handle must then be elevated so as to depress the point of the blade; that is to say, the instrument should be used as a delicate lever, the centre of motion being the skin, which may be pressed upon gently by the back of the knife; and in this way an opening of the requisite size can be made in the fascia at the bottom of the wound, without enlarging the external aperture.

Having thus far accomplished the operation, the sharp-pointed knife is withdrawn, and a probe-pointed one is to be passed into the puncture through the skin, superficial fascia, layer of adipose tissue, deep fascia, and lastly the proper sheath of the tendon, and be now inserted a little further in, so as to get well between the posterior tibial and the tibia. When satisfied from the sensation communicated to the knife that the bone is on one side and the tendon on the other, all that remains to be done is to turn the edge towards the tendon, giving the knife a slight cutting motion, while at the same time the assistant firmly abducts and depresses the inner border of the foot.[1]

A distinct sensation of something having suddenly yielded can be perceived at the time of the division of the tendon; but if the case should have been previously operated on, this feeling may be very slight, in consequence of the adhesions existing between the original wound of the tendon and the adjacent parts.

As soon as this peculiar jerk is detected by the assistant, he should immediately relax the foot, and apply a dossil of lint over the wound, holding it there with the fore-finger during the division of any other tendons. If, as has happened, the artery is supposed to be cut, either from the escape of florid blood or from the blanched appearance and reduced temperature of the foot, it will only be necessary to apply instantly a graduated compress, and to roll firmly a bandage upon the foot and ankle. This, however, may require to be loosened if the color of the toes shows any indication of strangulation. If the operator is not ambidexter, he will find, in the operation for dividing the posterior tibial tendon of the right limb, that he had better stand on the left side of the patient with his back to the patient's face, whilst the assistant sits down in front, and holds the thigh with one hand while he steadies the toes with the other.

Taking, then, the mesial line of the inner aspect of the leg at about three-quarters of an inch above the inner malleolus as the true position of the tendon, the sharp-pointed knife is to be inserted perpendicularly, with its back towards the sole of the foot. It is thus made to divide the skin and deep fascia in the same way as was explained when cutting the left posterior tibial tendon. After this instrument is withdrawn, the probe-pointed knife may now be used to finish the operation, which in all other respects agrees with the section of the corresponding tendon on the opposite side of the body. The long flexor of the toes, owing to its proximity, is often partially or wholly severed at this operation on the posterior tibial.

---

[1] We have seen more than one straight sharp-pointed bistouri caché used instead of two separate knives. The best of these was in the hands of Dr. Dick.

Weis and Velpeau divide the posterior tibial tendon at its insertion into the navicular bone, the knife being inserted so as to meet the tendon about an inch (in the adult) below and in front of the inner malleolus. This plan is inapplicable to infants. In adolescents and adults this tendon is usually so prominent to the eye and touch above and behind the internal malleolus, that it is an easy matter to sever it by inserting the point of a narrow straight scalpel at the posterior edge of the tendon, directing it forwards between the tendon and tibia, so as to divide it without risk of injury to the posterior tibial artery or the internal saphena vein. It is unnecessary to give particular directions for division of the plantar fascia when needed, those given respecting operations on other tendons being amply sufficient. The direction of the knife should be from without inwards, *i. e.*, from the external margin of the foot towards the internal margin.

The division of the anterior tibial tendon in talipes varus should follow the section of the posterior tibial; the patient being in the same position, and the assistant still holding the limb, and pressing his finger upon the lint covering the puncture already made above the ankle. The operator should feel for the most prominent part of the tendon over the joint, somewhat nearer the malleolus than in the normal foot, and insert a sharp-pointed knife, with its flat surface towards the outer edge of the tendon; and having passed it well beneath, he should turn the sharp edge towards the tendon, whilst the fore-finger of the left hand is pressed gently over the part, to warn him of the approach of the knife to the surface. The assistant, who has been steadily abducting the foot during the operation, gradually relaxes his endeavors as he feels the tendon yield; and as soon as he perceives the distinct snap which is the result of its complete division, he should immediately relax his hold, and apply a small dossil of lint over the puncture.

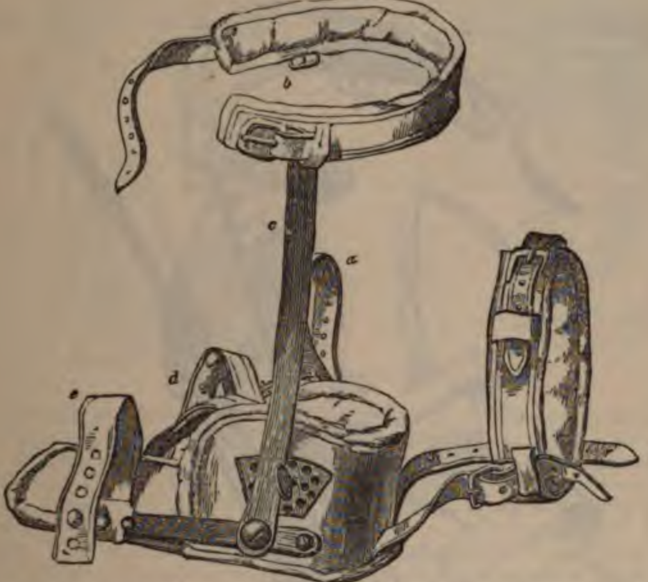
Division of the tendo Achillis is accomplished after turning the infant over on the abdomen. Whilst an assistant endeavors to bend the ankle, the surgeon introduces a small straight tenotome through the integuments from behind forwards at the side of the tendon. As soon as the point of the instrument is judged to have reached the anterior surface of the tendon, it is passed in front of it; the cutting edge is then directed to the tendon, severing the tense cord by one or two movements of the blade against it, and without wounding the integuments, except by the puncture of entry. The assistant should carefully relax the pressure he may be exercising upon the foot in proportion as he feels the part is cut through.

These operations, when properly done, occupy not more than a few seconds each, and are usually absolutely bloodless. Much has been written concerning the danger of wounding the posterior tibial artery. I have only once witnessed any trouble from the circumstance. This accident occurred to a former colleague. Ligature of the vessel on account of a small filbert-sized aneurism was required the third week after the operation. In that instance the wound in the vessel would have probably healed without aneurism if the surgeon had not too soon after the accident incautiously removed the bandage and abducted the foot. When injury of the vessel is suspected or known to have occurred, the removal of the bandage and commencement of the mechanical after-treatment should be delayed three weeks.

A pasteboard or soft metal splint, previously moulded to the form of the contracted part, should be employed immediately after the operation, to ensure quiet, and favor healing of the punctures.

Apparatus required after operation.—The metal splints already recommended for cases relievable without operation are equally applicable after division of tendons. Three days after operation, one of these splints, not much straighter than the affected foot, should be selected, or if a splint capable of being adjusted by a screw be used (fig. 693), it should be set at an angle or in a direction that the child will bear without complaint. In infants above the age of two or three months, a more elaborate and effective apparatus may be employed, when the pecuniary circumstances of the parents permit it. The woodcut, fig. 694, represents the lighest, the most effective, and the most inexpensive of the more elaborate apparatus constructed for the purpose. The perpendicular lever and the toe-spring are derived from Scarpa's shoe; but as Scarpa's apparatus contains no contrivance for depressing the heel, but relies simply on the effect of the weight of the body acting during locomotion, the author has introduced the movable thumb-screw, capable of being inserted into any required hole of the quadrant shown as above. This is an improvement upon the male and female screw, and the double acting ratchet-screws often used for the purpose. The simple arrangement of a movable thumb-screw has, in addition to lightness, the advantage of permitting mobility of the ankle in the direction of bending—a circumstance of much importance.

Fig. 694.



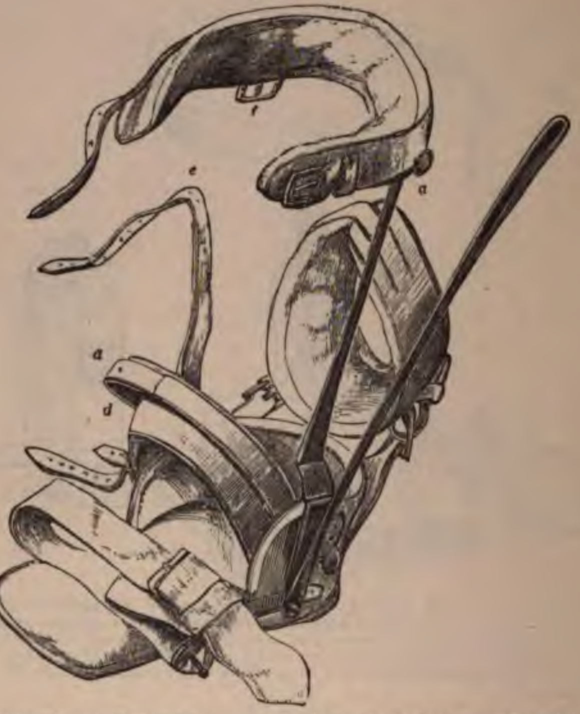
Dr. Little's Shoe for varus of left foot:—*a*, strap to be attached to the buckle *b*, intended to moderate the action of the lever-spring *c*; *d*, two straps which start from within the heel-piece on the outer side of the foot near the sole-piece, and are intended to be secured to buckles on the opposite side of the instrument, for the purpose of holding the posterior part of the foot firmly against the inside of the shoe, whilst the strap *e*, and short spring to which it is attached, draw the front of the foot outwardly. The convalescent may take exercise in this apparatus.

Cases of the first grade of infantile deformity are usually rectified in two or three weeks, those of the second grade in about four weeks, and those of the highest grade, the operation and the mechanical treatment having been divided into two or three stages, within two or three months. The treatment of adolescents and adults varies from two to twelve months.

Relapse not rarely occurs after the most complete flexion and abduction has been obtained. It takes place insensibly, at all ages, especially when growth is most rapid, and is due to too early discontinuance of instruments, and to neglect of manipulations, and of passive and active exercises. The worst so-called relapses result from previous incompleteness of operation or of restoration. No case should be considered finally cured until the mental development of the patient is sufficiently advanced for him to take an interest in his cure, and to be able voluntarily to hold the part in a perfect position, and perform the natural movements of it. In relapsed cases repetition of tenotomy is not commonly required. Often the *tendons* will be found of ample length; sometimes the diminutive belly of the gastrocnemius, for example, wasted through want of the stimulus of adequate alternate flexion and extension—*i. e.*, proper exercise — being shortened and drawn up towards the popliteal region. A common cause of relapse is doubtless the previous insufficient curative elongation of the fasciæ, ligaments, and muscles situated on the contracted side of the member, and is favored by the corresponding relaxation and weakness of structures on the opposite side. Continuous gentle re-application of the extending apparatus, aided, as soon as flexion to the right angle is reached, by exercise with a wedge of cork beneath the front of the sole, suffices to restore these cases usually within a few weeks—*i. e.*, within the period the patient would have been required to lie up if tenotomy had been repeated. It is satisfactory to be able, not only to spare the patient and friends the concern incidental to any operation, but to be able to avert, by mechanical means only, without loss of time, the discredit which attaches to the repetition of the operation.

In the treatment of relapsed adolescents, an apparatus that will bear the risks of walking exercise, and at the same time favor mobility of the ankle-joint in the required direction, is afforded by fig. 695.

Fig. 695.



Dr. Little's double-hinged upright Shoe for severe rigid Varus of left foot: *a*, stiff upright, hinged in two places, which when applied to the leg adapts itself to any degree of deformity; *b*, a spring curved outwardly, which when brought into contact with *a* can be then secured by means of a swivel-stud; *d d*, two straps for purposes similar to straps *d*, in last figure; *e*, moderating-strap, to be secured to *f*, as required. If the act of bringing the spring *b* into contact with *a* should occasion too much strain, *b* can be fastened at any required distance from *a*, by means of a tape. In the application of a varus shoe, success depends much upon the nicety with which the shoe is applied to the sole-plate of the apparatus, and upon careful adjustment of the power employed. The foot-part of the shoe should be properly applied before the upright lever is secured. The moderating-strap is the last to be fastened.

After operation for club-foot, even in infants, continuous application of splints or other apparatus is required for four or five weeks; in older children, for two or three months. The less severe the case, the more often the apparatus may be removed for cleanliness, and to examine lest undue pressure is employed. It is the boast of successful treatment of club-foot to be able to accomplish this result without a single excoriation. The surgeon should watch that, in his efforts to depress the heel and abduct the foot, the part be not too long maintained in one position, to the extent that the power of lowering the toes and of inverting the foot is lost; or, in other words, a valgus be engendered in exchange for the varus. This secondary valgus has been attributed to the non-union of the severed posterior tibial tendon. It is really due to too long-continued retention of the foot in an abducting apparatus. We have witnessed it in children born with varus, who had been treated without operation. Its production is favored by the same constitutional debility which produces spurious valgus, or flat-foot, in rapidly-growing children, who have previously had perfect feet.

Instrumental treatment is further required during at least a portion of each twenty-four hours, until the individual is enabled to plant the entire sole evenly and properly upon the ground, to thoroughly flex and extend the part at will, and habitually, when walking properly, to evert the toes. In numerous cases a child requires no apparatus after the age of five or six months; but the majority need some instrumental aid, such as leg-irons, to evert the entire extremity until the intelligence is sufficiently awakened—say, until the age of three years. The maintenance of the "cure" depends, as in all diseases, greatly, if not mainly, upon the individual or his natural guardian. We have had cases under observation off and on from infancy to puberty, owing to successive relapses, which have more commonly occurred abroad or in the colonies. We have witnessed examples of adults returning to be re-operated on, who have been successfully referred to their own efforts, with a few instructions as to mechanical attention.

Fig. 696.

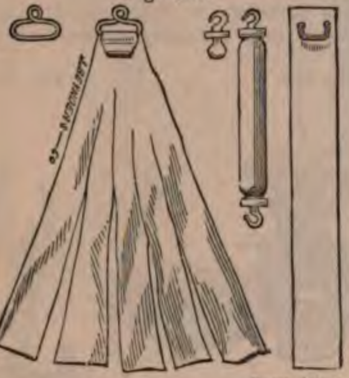


Fig. 697.

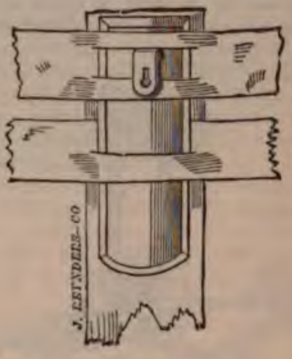

Barwell's appliances for club-foot.

[Surgeons are divided in their opinions as to the advisability of delaying replacement after tenotomy. English authorities have followed the teachings of Delpech and Stromeyer, and do not favor immediate extension. In this they are supported by many American surgeons, but opposed by Mr. Syme, of Edinburgh, Dr. Gross, of Philadelphia, and Dr. Sayre, of New York.[1] Dr. Buckminster Brown, of Boston, expresses himself strongly in favor of immediate extension in non-paralytic congenital varus, arguing that no risk is run in extending immediately, as over-extension is prevented by the contraction of the ligaments and fasciæ. After an extensive experience, he reports that he has never met with any bad results from such a practice.[1] This is also the practice of some German surgeons.[2]]

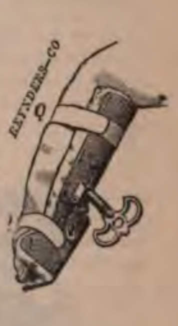
Fig. 701.



Shaffer's lateral splint applied.

After tenotomy no replacement of the part should be attempted until after the puncture has cicatrized. Much has been written respecting the propriety of immediate replacement. It is unnecessary in slight cases, and impossible in severe ones. In slight cases, nothing is gained by it; for if the position may be immediately rectified, the part cannot be immediately used. The limb should therefore be gradually replaced while the tendon is consolidating itself.

The influence, in interfering with union, of too-considerable and too early separation of the ends of a severed tendon, and especially of frequent motion, as in walking, is incontestable. Experiments upon animals have proved that considerable lengths of tendon may be excised, and union nevertheless ensue; but the knowledge possessed of the great extent of the powers of the economy is an insufficient reason for neglect of those rules of caution which experience dictates. The immediate separation of a severed tendon to too great an extent should be avoided. Half or three-quarters of an inch may be safely borne, although as a rule gradual separation is preferable. The condition of a severed tendon approaches that of a fractured bone; too great separation of the severed ends, depression of temperature sufficient to suspend active arterial circulation, too early movement of the parts, and inherent vice of constitution, may cause tendon, like bone, to remain ununited.

Shaffer's extension-shoe for club-foot.

Stromeyer has suggested, that previously to operation the patient should be accustomed to wear the replacing instrument. This plan is desirable when the practitioner is unfamiliar with the treatment of deformities; for he thereby becomes versed in the action and mode of application of the apparatus, and is rendered certain beforehand of the appropriateness of the contrivance.

[A great variety of appliances have been devised for the treatment of club-foot, and recommended by different surgeons as successful in their experience. A detailed description of these is impossible in this article; their nature, however, will be seen by the accompanying illustrations.

It may be said, however, that whatever

appliance may be used, the success of treatment will depend upon the thoroughness with which it is applied.

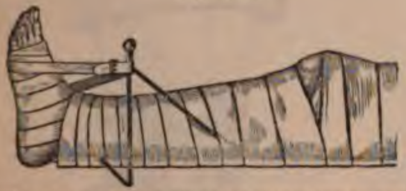
Fig. 710.



Mr. Davies-Colley's splint for talipes equino-varus (Bryant).

The treatment of club-foot by means of a plaster-of-Paris bandage has been recently again brought to notice, and is useful for a class of patients too poor or to careless to attend to the detail needed in the application of apparatus.

In such cases, excellent results in correcting the deformity can be brought about by plaster bandages, frequently renewed.

After tenotomy has been performed, which should be done, except in the slightest cases, the foot should be bandaged with a soft bandage, and the foot brought into position as far as possible and held during the application of the bandage by means of loops of adhesive plaster, held by an assistant, one being placed over the toes and pulled outward, and the second over the instep and pulled inward. When it is necessary to correct the equinus position, and to rotate the anterior part of the foot, it is necessary for the toes to be held in the proper position while the plaster bandage is applied. The bandage should be renewed in a few days in order to farther correct the deformity, and to prevent the formation of chafes. The danger of this latter is less than would be imagined, if the bandages are applied with care, and by one who is skilled in such procedures. But little more time need be expended than is frequently necessary for the proper adjustment of club-foot shoes. The bandages can be removed and reapplied daily, or frequently can be left untouched for a fortnight. The frequency of renewal should depend upon the need of increased correction of the deformity, and the amount previously gained.

The advantages of this method are that it is inexpensive and fixed, and also free from discomfort to the patient, the bandages being as a rule less uncomfortable than a Scarpa's shoe frequently is.

The chief disadvantage is the clumsiness of the appliance.[1]]

With reference to the choice of the apparatus, Stromeyer has rightly remarked, that every practitioner will select that of which he best understands the action and mode of application. This sagacious observation explains also one cause of the zeal with which each writer advocates his particular appliance.

It cannot be too strongly insisted upon, that in a large number of deformities, whether treated with or without operation, expensive instruments are unnecessary. More depends upon the tact, patience, and perseverance of the practitioner than upon the particular apparatus employed. Common roller bandages, with or without starch and plaster-of-Paris, tin, wood, or gutta-percha splints, aided by manipulations, may, in ingenious hands, supply the place of the most elaborate contrivances.

It may sometimes happen that no instrument is available, and the after-treatment may require to be conducted entirely by manipulations. Thus an adolescent case of double congenital varus was admitted into the London Hospital, under the care of Mr. Critchett, presenting large ulcers with necrosis on the dorsum of each foot, induced by pressure during the mechanical treatment after tenotomy. As the unhealthy character of the ulcers depended upon want of air and exercise, and the application of suitable instruments was impossible, it was determined not to wait for cicatrization of the ulcers, but to repeat tenotomy, and effect forcible manipulations of the members. Chloroform was upon one occasion employed. By these means the feet were gradually straightened, cicatrization of the ulcers was thereby favored, and within three months the lad quitted the hospital entirely restored.

After congenital varus, as after ac-

[[1] Ogston, Edinburgh Med. Journal, Dec., 1878, p. 482; Reeves, Med. Times and Gazette, Oct. 25, 1879, p. 475; Hutchison, Orthopedic Surgery, New York, 1880.]

quired deformities, retentive apparatus may be required; these for the most part consist of jointed irons to support the weak articulations, and springs to assist the action of the debilitated muscles.

The completeness of recovery in the great majority of the cases of congenital varus constitutes one of the triumphs of surgical art.

During childhood congenital varus may be entirely cured, without other traces of deformity than smallness of the member, greater squareness of the front of the foot, and sometimes less complete mobility of the ankle-joint, the patient recovering entire volition. When the case is unattended to before adult age, the internal margin of the foot may never be completely applied to the ground, owing to the impossibility in some cases of perfectly unfolding the os cuboides from its inferior and rotated position in the tarsus; in other instances, owing probably to the round head and neck of the astragalus having become so much inverted in relation to the remainder of the bone, that part of the undue convexity of the tarsus outwards becomes irremediable. Every year reduces the number of adult cases of varus requiring treatment, so that the consideration of any means of meeting the attendant difficulties may appear superfluous. The author has usually found a most efficient agent in a firm pad placed in the sole beneath the os cuboides, pressure being at the same time made upon the upper surface of the other tarsal bones.

Kolbé's improved club-foot stretcher.

[Dr. Benj. Lee, of Philadelphia, has reported the cure of a severe relapsed case of talipes equino-varus, where tenotomy alone and mechanical treatment appeared to be of no avail, by the successive application of force, under an anæsthetic, repeated every third day for three weeks; the subsequent employment of apparatus completed the cure;[1] he has also used a Morton "club-foot stretcher"[2] after tenotomy, to advantage.

Operative interference in old relapsed cases, by removal of pieces of bone from the tarsus, was suggested first by Mr. Little, and first performed by Mr. Solly, who excised the cuboid, at St. Thomas's Hospital, in 1854, and with an improvement, but not a perfect success.[1]

Mr. Lund subsequently removed with success the astragalus, to a large extent correcting the deformity, but not leaving a perfect foot.[2]

This operation has been successfully

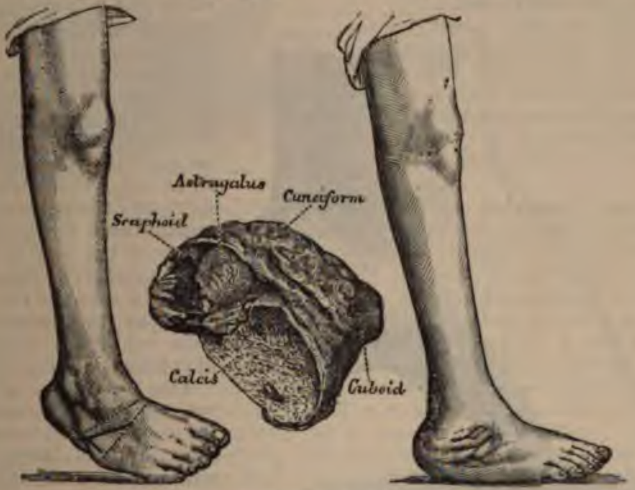
repeated by Mr. Lund himself,[1] Mr. Thomas Smith and Mr. John Wood.[2]

Dr. Mason, of New York, was unsuccessful in attempting to cure a deformity in this way, and his patient died after amputation. Terbelzi reports a successful case.[3] Mr. Davies-Colley successfully resected a wedge-shaped piece from the tarsal bones, in an extreme case of talipes equino-varus. The patient was twelve years old; both feet were affected, and were operated on successively after an interval of two months. The result is reported to have been excellent, the patient being able to place the whole sole upon the ground, and within a year of the operation to walk six miles.

This operation has met with favor in Germany, and successful cases have been reported by Mensel, Hueter, Schede, König, Rupprecht, and Ried; and in England by Messrs. Bryant, West, and Barwell. In one of König's five cases death followed ten days after the operation; but on a post-mortem examination, ulcerative endocarditis with pathological changes were discovered. In none of the other reported cases did death occur. The operation in the hands of German surgeons was not confined to adults, but used in children as young as four years of age.

Mr. Davy, who reported three cases of excision of the cuboid bone for club-foot, became convinced that more of the tarsus must be removed; and in three other cases removed a wedge-shaped piece from the tarsus. In one of these the patient was a child of sixteen months. The result is said to have been satisfactory in all the cases; but in those where the cuboid alone was removed, greater improvement in position could be hoped for. In one later case of talipes equinus, a wedge-shaped piece was removed, but death from septicæmia followed.

Fig. 713. Fig. 714. Fig. 715.



Mr. Davies-Colley's operation for talipes equino-varus.
Fig. 713. Foot before operation. Fig. 714. Bones removed. Fig. 715. Foot after operation (Bryant).

In this case apparently, as in Dr. Mason's, antiseptic precautions were not employed.

It would appear, therefore, that with the use of antiseptic dressings, the operation is a comparatively safe one; and although it is certainly bad surgery to resort to excision in young children, or in cases where the ordinary treatment by tenotomy and apparatus can be used, the procedure is justifiable and called for in inveterate cases where circumstances prevent the correction of the deformity in the usual way.

The incision necessary for this operation is either a curved one along the outer border of the foot, beginning below the malleolus, and reaching nearly to the small toe, or a shorter incision with a cross cut reaching over the dorsum of the foot. The latter is used by Mr. Davies-Colley, Mr. Davy, Mr. Bryant, and others; the former is recommended by Mr. West, and was used in a successful case by Dr. Porter, of Boston, and by the writer in two satisfactory operations.

Tenotomy appears not to be always necessary either before or after the operation, although it is not contra-indicated. The amount of bone to be removed varies necessarily in different cases. Mr. Davies-

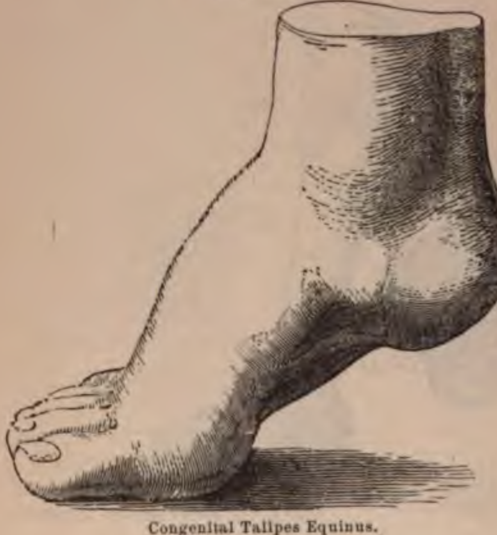
Colley removed the cuboid entirely, a portion of the head of the os calcis, and the astragalus, a large part of the scaphoid, portions of the three cuneiform bones, and the heads of the two outer metatarsals.

Ried mentions having operated by boring through the astragalus and the malleoli, and inserting a key-hole saw with which the bone was sawn in two directions, so as to separate a wedge-shaped fragment.[1]]

Congenital Talipes equinus, Talipes equino-varus, Talipes valgus, Talipes equino-valgus, Talipes calcaneo-valgus, and Calcaneo-varus.

By talipes equinus is understood morbid contraction of the muscles of the calf, and consequent depression of the toes, the adductors being unaffected. This is a very rare *congenital* affection. We have met with two cases in the same family—the first-born, and the last child, the eleventh. When it has not been treated in infancy, locomotion is effected on the inferior extremities of the metatarsal bones and phalanges. In severe cases the internal margin of the foot is slightly inclined inwardly, and the metatarsus is projected forwards. There is not, as in varus, any disposition to tread exclusively on the outside of the fifth metatarsal bone.

Fig. 716.



Congenital Talipes Equinus.

The existence of congenital talipes equinus has been emphatically denied. It is a question of fact and capability of discrimination. It may be suspected that the rare cases of congenital equinus which may have fallen under the observation of those who have denied its existence have been erroneously classed as varus. In congenital contraction of the muscles of the calf, owing to the morbid elevation of the heel, the narrow portion only of the trochlea of the astragalus is retained within the malleoli, and the front of the foot falls or is drawn readily either inwardly or outwardly; the more ready or usual direction being inward; just as we see in some sound children there is a preponderance of the adductors (tibiales) over the peronei, and the feet are consequently observed to be turned in more often than out. Consequently the surgeon who makes no allowance for the ordinary tendency of the feet to incline, and who considers a case to be varus when he sees the foot with never so slight an inward inclination, does not believe in the existence of congenital talipes equinus.

The few cases of unoperated congenital adult equinus which we have seen have remained talipes equinus throughout. The patients have continued to walk on the metatarsal extremity of the great toe, as well as on the little toe.[1] The great toe has never been raised from the ground, as it is in congenital varus. No original or secondary affection of the adductors had drawn the foot in, so as to resemble congenital varus or even non-congenital equino-varus. The patient, we repeat, still walked on the great toe and the little toe.

If congenital equinus be rejected upon the ground that must be taken by those who deny its existence, then it may as justly be asserted that neither does non-congenital talipes equinus exist; for there

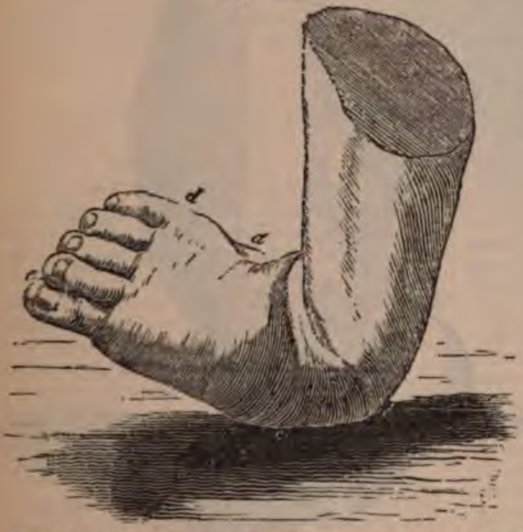
[1] We have recently examined an adolescent with well-marked hereditary congenital equinus. It was further remarkable by constituting the fifth example of the deformity in living members of the family, viz., the father, two paternal uncles, and one aunt.

is no non-congenital talipes equinus in which a trace of inversion or of eversion cannot be discovered, which when very marked is termed either talipes equino-varus or talipes equino-valgus.

Fig. 717.



Front view of a congenital Talipes Valgus of the right foot of a boy aged four years: *d a*, the outer edge of the foot raised from the ground; *e*, the great toe raised from the ground, although the internal edge of the foot is directed towards it; *b*, the internal malleolus; and *c*, the internal extremity of the navicular bone, being the parts upon which the patient walked.

The dispute as to the existence or non-existence of congenital talipes equinus continues for the same reason that discussion is endless in every department of natural history, as to whether a given object belongs to one species or forms another species; one observer recognizing a radical difference, which another observer either overlooks or explains away as belonging to another species.

Talipes valgus, equino-valgus, and calcaneo-valgus, are the terms applied to those distortions which contrast most with talipes varus, or ordinary club-foot. The front of the foot is more or less turned out in each of these varieties, instead of being inverted as in varus. In valgus the peronei are the muscles mainly contracted; in equino-valgus the tendo-Achillis is also tense, and the heel elevated, the toes at the same time pointing outwardly. In calcaneo-valgus the heel is depressed through the contraction of the anterior tibial, and the toes pointed outwardly from tension of the peronei.

The foot-deformities named respectively equino-varus and equino-valgus are both non-congenital, and offer other points of analogy, the chief of which is their dependence upon either spasmodic or paralytic contraction as the case may be.

The reader, on comparing fig. 719 with fig. 691, will perceive the similarity of form between equino-varus (a non-congenital affection) and congenital varus, and might reasonably conclude that little reason exists as far as external form is concerned for making any distinction between them. An essential difference is, that congenital varus is fully formed at the time of the child's appearance in the world, whereas equino-varus, when it proceeds from paralysis, is gradually produced, slowly attaining the maximum of distortion. In spasmodic equino-varus also the distortion resulting from either obvious or obscure disorder of the nervous system is rarely complete *ab initio;* on the contrary it is for the most part slowly developed. The analogy of equino-valgus (fig. 720) in some respects with equino-varus is apparent. In both there exists contraction of the tendo-Achillis; both are produced after birth from either spasms or paralysis. In equino-valgus the toe is everted, and not inverted as in varus.

The deformed, enlarged, and protuberant heel of talipes calcaneo-valgus is the consequence of several years' locomotion on the posterior extremity of the os calcis. This bone has in effect, in the fully-developed deformity, a nearly vertical instead of the nearly horizontal position which obtains in the well-shaped foot.

The rules already laid down for judging of the necessity for tenotomy in varus and of the number of contracted tendons to be divided, apply to each of the distortions now under consideration. The principles which should direct the mechanical treatment are equally applicable. The experience of the surgeon and the ingenuity of the instrument-maker are required to adapt the apparatus to the peculiarities of each case.

A variety of congenital varus occasionally presents itself, in which the inner margin of the foot is slightly raised, the sole contracted, and the dorsum prominent towards the outer side of the foot, but without elevation of the heel. In these cases the muscles of the ankle are unaffected. We have designated this affection calcaneo-varus. The treatment consists in making pressure by means of a pad upon the prominent dorsum, and in suitable manipulations. A beneficial result is soon observed; but the affection is prone to return. Division of the plantar fascia and of the long flexors of the great toe rarely exercises as much perma-

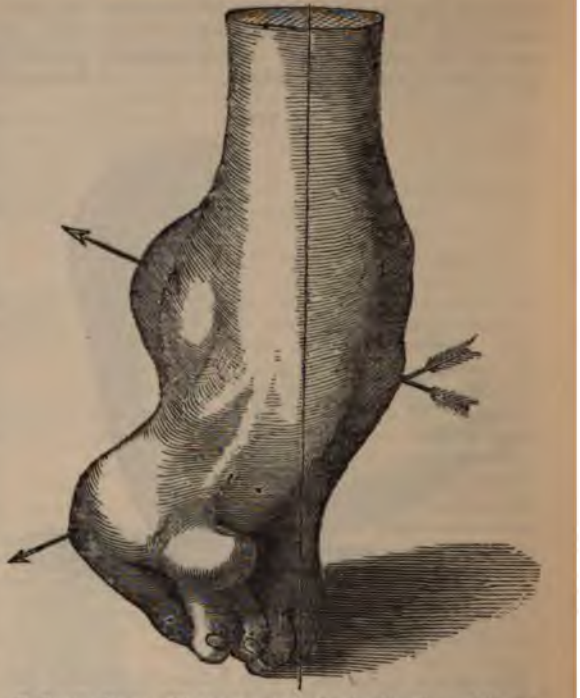
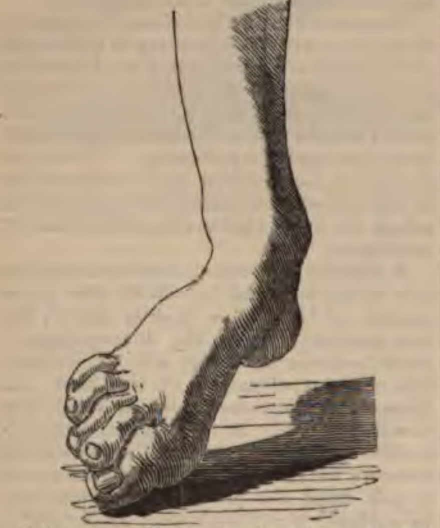
Fig. 719.



T. Equino-Varus. The arrows indicate the direction of the convexity of the tarsus and metatarsus, forward and outward; the perpendicular line through the axis of the limb shows the extent of the inward deviation of the metatarsus, by which the base of the little toe, being brought completely beneath the axis, has to support the entire weight of the body in walking; and is, in consequence of its attrition against the ground, a considerable cause of suffering.

Fig. 720.



Talipes Equino-Valgus, from loss of power in anterior tibialis, and consequent contraction of calf muscles, and of peronei.

nent benefit as is expected, because the quantity of plantar textures necessarily left unsevered suffice after cessation of the treatment to reproduce contraction.

Some irregular *congenital* foot-distortions are met with. In a few of these we find distinct paralytic loss of muscular power: in one case well-marked paralytic varus, with much atrophy of the soft and hard parts; in another, paralytic contracti[illegible]n of the hips, knees, and feet, with implic[illegible]ation of the upper extremity. The o[illegible]ly treatment applicable is to relieve contr[illegible]ction by manipulation, friction, and in [illegible]nyielding cases by tenotomy, thus offer[illegible]g

Fully developed Calcaneo-Valgus, from paraly[illegible] of gastrocnemii and consequent contraction of muscl[illegible] of the sole, of anterior tibial, and peronei muscl[illegible] In some instances the anterior tibial shares the f[illegible] of the gastrocnemii.

a chance to the muscles which remain partially under the will, to support the individual in attempts to effect imperfect locomotion. We have watched these cases from birth to adolescence; in many the paralysis has remained undiminished.

[Yost mentions a child born with marked talipes equino-varus of one foot, where a spontaneous cure took place in three months, without attempt at treatment.[1]]

Distortions originating at the moment of Birth.

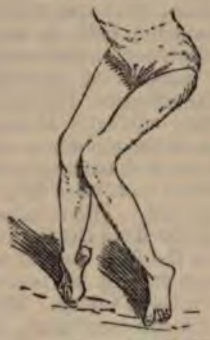
We have seen that in the earliest times of the study of congenital distortions, they were successively attributed to the anger of the Deity, lusus naturæ, malposition in, and pressure of, the uterus. In the present day, an enlarged observation of non-congenital as well as congenital distortions leads irrefragably to the conclusion, that the numerous causes which are found to operate in the production of distortion after uterine existence, exercise analogous if not identical effects, whilst the fœtus remains within the uterus. These causes are, hereditary and maternal influences, disturbance of the nutritive, respiratory, circulatory, and nervous systems of the fœtus and infant, accidents, entanglement by the funis and abnormal bands, intra-uterine fractures, malposition and pressure, fixed repose in one position, and inflammation. In order to illustrate the obnoxiousness to distortion existing at every epoch, we shall here describe a group of distortions, which unquestionably take their origin at the period intervening between uterine and independent life, that is, *during* birth. We believe we can particularize the moment, as that moment which connects placental with pulmonary respiration. When we reflect upon the important phenomena in the economy at that moment when it should adapt itself to the immense changes involved in the abrupt transfer of the oxygenating process of the blood from the placental to the pulmonary cell-surfaces, we should anticipate that any retardation, interruption, or arrest of this transfer of the most important function should be attended with the greatest evil to the system at large, and especially to the nervous system, the most susceptible in the body.

We know that a state of suspended respiration and animation is the common consequence of many of the accidents attendant upon birth; and we might infer, from the evils often witnessed after recovery from the asphyxia of drowning or of choke-damp, what might be the consequences of the apnœa and asphyxia of new-born children. Some of these appear, however, to have escaped notice, until the observations published by the author in 1843. The lungs suffer in the form of atelectasis; the heart probably in delayed or deficient closure of the foramen ovale, and possibly in straining of its walls; the nervous centres from effusions and apoplexy, followed by impeded developments, atrophy of individual parts, sometimes by impaired intellect and volition, convulsions, and spasmodic contractions.

It is scarcely necessary to add, that difficult and instrumental labors, and those in which the cranial bones and brain, and even the vertebræ and their contents, have suffered mechanical injury, are more likely to be followed, if not by death, at least by general convulsions and other serious derangement of the nervous system, of which a prominent symptom are the "internal" or subdued convulsions of the nursery.[1]

A common class of affections resulting from injury at birth, whether the injury be mechanical or vital, consists of a peculiar diminution of volition with tonic rigidity, in varying degrees of a part or of the whole of the muscles of the body, described as, "the spastic rigidity of new-born children." Both lower extremities are more or less generally involved. Often

Fig. 722.



Spastic contraction of flexors and adductors of the lower extremities, consequent on asphyxia neonatorum. Similar distortion may result from "convulsions" during teething, and from other cerebro-spinal affections.

Club-foot caused by congenital absence of the tibia, Berliner Klin. Wochenschr., May 19, 1879, p. 297; consult also on this subject, Wolff, Arch. f. Klin. Chir., xxi., p. 90; Morton, Philadelphia Med. Times, Oct. 9, 1880, p. 25; Shaffer New York Med. Record, Nov. 23, 1878.]

[1] See Transactions of the Obstetrical Society, 1862.

one limb only is referred to by the parents; but careful examination usually shows a smaller degree of impairment in the limb supposed to be unaffected. This state of peculiar spastic rigidity of young infants may even continue through the whole duration of life. We have known patients over forty years of age thus affected from birth.

The amount of contraction in the hips, knees, and ankles is often considerable, and the leanness proportionate to the contraction. The flexors and adductors of the thighs, the flexors of the knees, and the posterior muscles of the legs preponderate. The thighs and knees cannot therefore be completely extended, or the heels be applied to the ground. In some cases the upper extremities are held down by the preponderating action of the pectorals, teres major and minor, and latissimus dorsi; the elbows are semi-flexed, the wrists partially flexed and pronated, and the fingers incapable of perfect voluntary direction. Participation of the muscles of the trunk is sometimes shown by the shortened, flattened aspect of the pectoral and abdominal surface, as compared with the more elongated, rounded form of the back. The prominence of the back partially disappears on recumbency; but the greater weakness of the muscles on the dorsal aspect of the trunk is obvious when the individual again attempts to sit upright. The inability and indisposition to exert the abdominal and other muscles concerned in the expulsive processes may, perhaps, sufficiently explain the tendency both to rare micturition and defecation, which sometimes exists. The muscles of speech are often involved, the affection varying in degree from inability correctly to utter one or more letters of the alphabet, up to the entire loss of the articulating power. During the earliest months of life, deglutition is often impaired. The intellectual functions may suffer from the slightest impairment, which the fond parent unwillingly acknowledges or fails to perceive, up to entire imbecility or idiocy. The functions of organic life are unaffected, except perhaps that of development of caloric, although the depression of temperature may be more dependent on the want of proper exercise. The appetite is good; the frame generally, in average cases, is well nourished, although with less than the average adipose deposit. The child is often described as the healthiest of the family, escaping epidemics, or having these disorders less severely than the brothers and sisters. These subjects often lead a more precarious existence during the first weeks after birth; at first even vegetative life languishes, often because premature birth or difficult labor, by impairing the maternal supply of nutriment, renders more difficult the infant's recovery from the shock the system has received. However, in the majority of instances, after restoration of the vegetative functions, a gradual amelioration of all the functions of animal life is perceptible.

Although at first convulsions are the rule, the *spastic* contractions are not present, or are not observed, until some weeks after birth. The child's limbs are simply weaker; the convulsions and the question of viability alone occupy the thoughts of the attendants. Before the age of three or four months, though sometimes in slight cases not until the ordinary time for locomotion has arrived, the nurse perceives that she is unable properly to separate the thighs or knees for purposes of cleanliness; that the child never thoroughly straightens the knees; that he does not attempt to stand, or is incapable of standing except on the toes, or that the feet are disposed to cross each other. Even children slightly affected rarely "go alone" before the age of three or four years; many are unable to raise themselves from the ground at that age, and others do not walk even indifferently at puberty. Locomotive ability seems to advance in proportion as the intellectual powers are developed. The external form of the cranium occasionally exhibits departure from the normal type—such as general smallness of the skull, depression of the frontal or occipital region only; sometimes of one lateral half of the skull, sometimes of one-half of the occiput only.[1] In slight cases the head has been well developed. The *ensemble* of phenomena points to injury more or less extensive of the cranial contents, and especially of the medulla oblongata and spinalis.

In all cases, even with great inertia as to the exercise of volition, common sensibility appears little if at all deficient. On the contrary, a morbid sensibility of the organ of hearing and of the cutaneous envelope appears to exist, evinced by "startling" at the slightest noises, and extreme sensibility to touch. This morbid sensibility may be due to a condition of spinal cord analogous to that present in narcotized frogs, in individuals under the influence of strychnine, or those affected by tetanus. It may, however, be apparent only, dependent upon the individual, when subjected to common noises, being less competent quietly and promptly to reason upon them, and by thus reassuring the easily disturbed nervous mind, to escape from the exciting influence. In many cases the intellect has been intact.

---

[1] Morbid anatomy reveals in these cases a corresponding deficiency in size of the affected parts of the cranial contents.

A peculiarity of these children—an uncommon fear of falling—is often observed when they are seated on a couch, less when they are on the floor, and not observed when they are seated in an armchair; a circumstance clearly due to conscious inability to balance and recover the position of the body.

Spastic Contractions from Cerebro-spinal Disease in Infancy and Childhood.

We have just described a state of more or less general spastic contraction, which results from disturbance of the cerebrospinal centres at the moment of birth, either from direct injury to the cranium or neck whilst passing through the maternal parts, or, more probably, from asphyxia consequent upon interruption to the substitution of pulmonary for placental respiration. Sometimes, without either premature or difficult labor having preceded, convulsions occur very soon after birth, during the first hours, days, or weeks of independent existence. Convulsions, as is well known, occur more frequently after dentition has made some progress, whilst the infant is undergoing another transition, that of passing through the crisis from nourishment by the mother's breast to feeding, when unfavorable consequences of deprivation of breast-milk are apt to show themselves. The infant may be of previously unexceptionable history, except that the parents may be the subjects of disorders of the nervous system, of nervous temperament, have overtasked brains, have been phthisical, or are intemperate. These convulsions now and then leave the sufferer impaired in mental power, and affected with spastic rigidity, undistinguishable from that which succeeds apnœa and asphyxia neonatorum. (See fig. 722.) It is scarcely necessary to add to the previous remarks on spasmodic and paralytic contractions that convulsions and other cerebro-spinal morbid states of childhood may be followed by spastic contraction, or paralysis of single muscles or of sets of associated muscles.

[Dr. Sayre has called attention to a variety of reflex partial paralysis resulting from genital irritation and relieved by circumcision. The forms of nervous disturbance observed are chiefly incoördination of motion, more rarely muscular spasm.[1]]

Treatment.—The indications for either the operative or mechanical treatment of these different forms of spastic and paralytic contractions, and the mode of conducting the treatment, are the same as those laid down in speaking of congenital club-foot (p. 335), modified by the nature of the cause of contraction. In contradistinction to congenital contractions, we may remark, that in contractions occurring during teething, the occurrence of structural shortening may generally be prevented by timely-applied manipulations, frictions, mechanical support to paralyzed parts, or assistance to the antagonists in the case of spastic affections. It should be remembered as a reason for avoiding unnecessary tenotomy, that the contracted muscle is often the healthier one, and that in the case of a spasmodically affected muscle, tenotomy does not "cure" the spasm. It is often only temporarily beneficial, and sometimes transfers the preponderance to another set of muscles, merely substituting one evil for another. In severe general spastic contraction, the surgeon has carefully to balance the good and evil, one against the other.

Flat-foot, or spurious Valgus.

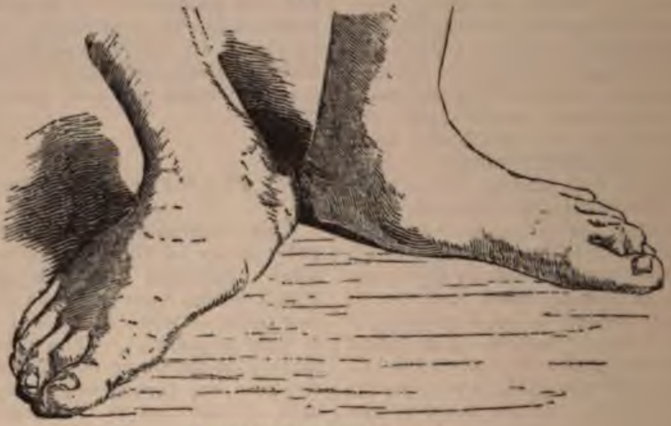
This common deformity presents externally many of the characters of congenital valgus, and of the acquired valgus which results from paralysis of the anterior tibial muscle. But the resemblance is only superficial. The person treads unduly on the inner margin of the foot, the toes are turned outwardly, and the arch of the foot is diminished, or, in severe cases, may be obliterated; hence the term flat-foot. True valgus springs from congenital contraction of the peronei muscles; spastic non-congenital valgus from spasm of the peronei; paralytic valgus from partial or total paralysis of the anterior tibial; sometimes combined with paralysis of the posterior tibial, causing contraction of the peronei owing to the want of antagonists; but spurious valgus or flat-foot is due to general want of tone in the fibrous structures of the body,—displayed in the yielding of one of the parts of the frame most exposed to strain, the plantar muscles and ligaments; hence sinking of the arch, eversion of the toes, and secondary contraction of the peronei. After a time the displacement of the tarsal bones, connected with the sinking of the arch, leads to painful or difficult locomotion and limitation of the movements of the ankle-joint. Finally, the tarsus may be said to be convex inferiorly, concave superiorly, the anterior part of the foot being then drawn up by the conjoint action of the anterior tibial and the extensors of the toes, and the heel held tensely upwards by the muscles of the calf. Even in moderate cases contraction

---

[[1] Sayre, Trans. Am. Med. Assoc., 1875; Hamilton, Am. Journal Med. Sciences, Oct., 1879; Yale, New York Med. Journal, Aug., 1877.]

of the peronei is distinctly felt; in severe cases shortening of the remaining muscles above enumerated is also evident. In the worst cases scarcely any mobility of the ankle-joint remains. A slight degree of flat-foot is common in girls, especially amongst those of fine organization in the upper and middle classes of society; less frequent in boys; and is curable amongst them by considerably reducing the amount of standing and walking exercise, by substituting horse exercise where practicable, by avoiding too fast walking in the company of adults, by early hours, by avoiding competitive over-study, by generous living, fresh air, tonics, attention to the state of the primæ viæ, embrocations, and manipulations directed to the promotion of inversion of the foot and prevention of the threatened contraction. In greater relaxation of the parts about the inner ankle, actual confinement to a couch, and carriage-exercise for a month or five weeks, or that time spent on the sands or beach at the sea-side, will lay the foundation for cure. Laced boots, supported at the sides with stiff leather or thin steel busks, are of great assistance in walking. An elastic horse-hair, India-rubber, or felt pad beneath the inner margin of the foot tends to support the arch. Iron and cork, often employed for this purpose, are harsh and inefficient. We must utterly condemn a practice often resorted to in contempt of the pathology of the affection—that of severing the peronei and tendo Achillis in all such cases. The recovery of patients from moderate flat-foot when this operation has been performed, is due mainly to the absolute repose of the limb with which the operation is followed, and to the mechanical measures concurrently employed. But in a few rare cases in private practice, and in those of boys who have stood prematurely behind a counter twelve or fourteen hours daily, and amongst the lower classes in public institutions who have suffered from premature labor, the deformity has existed so great a length of time that the contracted muscles have become shortened and rigid, rendering tenotomy, with its promptness and certainty of action, a necessary adjunct to the mechanical treatment.

Fig. 723.



Severe flat-foot or spurious valgus.

Flat-foot often exists for several years without attaining even an intermediate grade of severity, when all at once a particularly long walk, a leap, or initiation into a standing occupation, becomes the starting-point of a considerable and rapid aggravation. Sometimes evidence of chronic inflammation of the calcaneo-scaphoid ligament, or other plantar structures, or a painfully stretched condition of the plantar nerve, exists. This last symptom is recognized by the exquisite, unbearable, electric-like, painful, tearing sensation described by the patient when he takes a long stride, or stands on the affected leg alone. We should not be induced to operate on flat-foot even on account of its long duration, or of palpable shortening of the tendons before enumerated, since even rigid contraction of muscles, healthy as to their innervation, will yield in a few weeks to judicious frictions, manipulations, disuse of the part (required in this deformity owing to its special exposure to aggravation by walking), and mechanical treatment. As an argument in favor of severing the Achilles and other tendons in slight cases, we have heard the question put, "What harm does the section do?" Now, although the tendo Achillis is very tolerant of the ever-ready operator's scalpel, it cannot be pretended that an unnecessary operation is a benefit. As, in extremely severe cases, the act of walking, after replacement of the tarsal bones, tends to bear down again the tarsal arch, the aid of mechanical appliances is subsequently needed for several months, or even sometimes for two or three years. Relief is much more readily obtainable in the child than in the adult. The apparatus available in these cases is the same as that used for varus, but with the action of the springs, screws, or lever reversed.

Subcutaneous division of the peroneus longus and brevis is effected in a manner similar to the operation of severing the tendo Achillis. The patient should lie over on the opposite side, an assistant holding the foot inwardly, so as to maintain extra tension of the parts. The tenotome should be introduced in front of the tendons, the section proceeding from before backwards.

[Cases of slight talipes varus following a previous osteitis of the lower end of the tibia are to be mentioned; in one case coming under the observation of the writer, recovery from the osteitis had taken place without involving the ankle-joint, but a troublesome valgus resulted.

Either varus or valgus may occur from absence of the tibia, or from an abnormal shortening resulting from previous disease.]

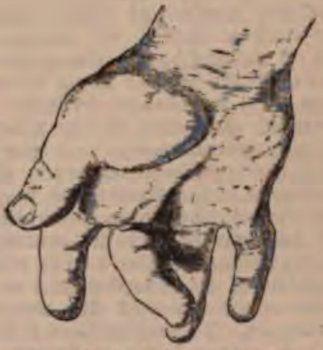
Contractions of the Upper Extremity from Spasm and Paralysis.

The principles which should direct the application of tenotomy to spasmodic and paralytic contractions of the upper extremity are those which are applicable to other parts of the body, except in so far as the functions of the individual muscles of the upper extremity, especially those of the wrist and fingers, are more delicate, varied, and complex than, for example, are those of the corresponding parts of the lower extremity. We should be prepared to expect that a surgical proceeding which aims at intercalating a piece of new tendon, with the object of reducing the range of action, and therefore the power of a rebellious spastic muscle, or for the purpose of thereby weakening a healthy muscle so as to favour a partially paralyzed antagonist to recover its activity, would be less successful than in the lower extremity, the actions and movements in which are comparatively simple. The acquirement of the power of progression, even if it be incomplete, amply compensates for the sacrifices the patient makes; in bad cases he is satisfied with the possession of a limited flexion and extension of the hip, knee, and ankle, and can be aided by mechanical appliances. But in the case of the wrist and fingers the individual derives little benefit from these simple movements, and he cannot be materially assisted by any complicated mechanism hitherto invented. We have divided the biceps at the bend of the elbow, the rigid well-defined pronator radii teres at its muscular portion, the tendons of the flexor carpi radialis and ulnaris where most prominent close to the wrist, and have found the resulting benefit proportioned to the attention subsequently bestowed upon manipulations, passive exercises, and painstaking education of the enfeebled non-contracted extensors. Except in cases of many years' duration, in which the retracted muscles were reduced to inextensible fibrous bands, it has seemed that as much ultimate benefit was obtained by manipulations and exercises as by the employment of an operation, and at no greater expenditure of time. The prognosis must be based on the amount of improvement that may be expected in the affected portion of the nervous centres. As an encouragement to treatment, the surgeon should remember that cases occur in which the disorder of the nervous system and nerves has ceased, and that he has to deal only with consequences. This observation applies also to many congenital contractions.

Deformity from Disease of the Palmar Fascia.

A not uncommon contraction in the upper extremity consists in a permanently flexed condition of one or more fingers, with visible and palpable thickening and hypertrophy of the fascia investing the palmar surface of the first phalanx of the affected finger, and of the neighboring portion of the palmar fascia. Sometimes the whole of the fingers and thumb are implicated, the palm itself is contracted,

Fig. 724.



Contracture of palm and fingers from disease of palmar fascia.

and the use of the member as a prehensile, and even as a tactile, organ almost destroyed. The ring and the little fingers, the middle finger, index, and thumb, are usually affected in frequency and degree in the order in which we have placed them. The articulations are commonly unaffected, although occasionally that of the first phalanx with the second phalanx, or this with the third, has exhibited slight arthritic enlargement. On endeavoring to straighten the fingers, the surgeon feels that a general resistance is offered by the tissues of the entire palmar surface of the hand and fingers, and especially by the indurated palmar fascia itself. Any existing tension of the flexor tendons cannot be felt along the fingers, but in the palm, particularly in the upper part, above the edge of the most indurated part of the palmar fascia, one or more prominent and tense tendons may be felt. This deformity is usually attributed to injury, often to a trifling wound, to irritation by the use of a whip in driving, of a walking-stick, or mechanical tool. These mechanical causes, or local irritants, if really operative, can be regarded only as occasional determining or exciting causes. The essential or primary cause is a constitutional one, allied to the gouty or rheumatic diathesis. We may not venture, however, to assert that the constitutional cause is identical with that of gout or rheumatism, as the persons affected have appeared singularly free from other manifestations of those affections. The disease of the palmar fascia, unlike gout or rheumatism, is painless. Many patients affected with considerably contracted palmar fascia in both hands present similar induration of the corresponding fascia of the soles; a sufficient proof that the complaint is essentially independent of the mechanical causes assigned for it,—unless, indeed, we assume that the act of walking by stretching the sole can act upon the plantar fascia after the manner of a mechanical irritant. The symmetrical character of the affection, the precise resemblance of one case with another, the occasional existence of hereditary gout in the family, the frequent occurrence of the same deformity in father and son for several generations (four), as well as the above facts, confirm the opinion of its constitutional origin. We have never witnessed this complaint in the female. Those who have freely indulged in strong wines and spirits, or beer, are frequent subjects of it.

We regard it, then, as a painless chronic induration of the fascia, leading to compulsory, gradually-increasing disuse of the fingers and hand. Through this disuse the flexor muscles and tendons, which are probably free from the original affection, assert their preponderance over the equally idle extensors, and become generally affected with secondary shortening.

Treatment.—Even in tolerably advanced cases, frictions, manipulations twice or oftener daily, the application of a screw-adjustment splint, or straight splints of wood, tin, or gutta-percha, will, if suitably and perseveringly used, reduce the contraction and deformity. But at the advanced age at which many patients present themselves for relief, the employment of mechanical apparatus encounters many difficulties. In rigid unyielding cases of long duration, tenotomy is remarkably efficacious. We cannot by its means alter the constitutional state, or directly remove the induration of the fascia; but we are enabled to remove by tenotomy the secondary tendinous contraction, to take the case entirely out of the influence of the patient's will, so far as the contracted muscles are concerned, and obtain a starting-point for further benefit by mechanical treatment. A puncture half a line in width suffices for the passage of a firm tenotome beneath the tendon in the palm. The tendon is thus divided from below upwards. No fumbling or unnecessary handling of the part after the operation, by which means air or blood might be disseminated amongst the palmar tissues, is permissible. The operation, like most subcutaneous operations, is bloodless. We have invariably seen the puncture heal within forty-eight hours. Considerable yielding of the contracted finger, the tendon of which has been severed, is at once perceived. Manipulations and mechanical treatment complete the cure. We have frequently thus effected entire restoration of the hand and fingers. It is remarkable that the indurated fascia softens, and the hard ridges and corresponding furrows in the fascia disappear, under this treatment. It is obvious that the afflux of blood to the part, excited and maintained by the frequent manipulations, frictions, and bandages, alters the nutrition of the part, and removes the previous morbid deposit. It is also probable that caution as to diet and wine whilst under the observation of the surgeon, assists this process of recovery. The causes being constitutional, and the attention of the patient being liable to slacken after a lengthened recovered use of the member, the complaint occasionally returns. We have re-operated on a patient thrice in eleven years; the individual expressing himself amply compensated for the operation by nearly as many years' good use of the part. This operation is a valuable illustration of the success of subcutaneous tenotomy compared with Dupuytren's painful operation, even when performed by so able a surgeon as the late Sir A. Cooper. We have had under observation two cases in which, by means of a large crucial incision of the palm, the indurated fascia had been dissected out and removed. The operation had no better result than that of causing a large contracted cicatrix, more rigid than the former state of things, and quite irremediable.

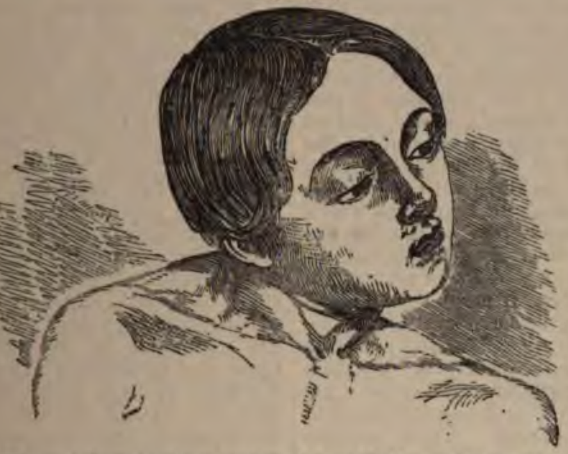
[Mr. Wm. Adams advises as a mode of treatment for Dupuytren's contraction, subcutaneous division of the palmar fascia and immediate extension. It is necessary to divide all the contracted bands of the palmar fascia, and for this purpose Mr. Adams uses a very small tenotomy knife, inserting it under the skin and cutting from above downward. The finger should be immediately extended and bandaged to the splint, which should not be removed until the fourth day. A splint should be worn night and day for three weeks, and at night for three or four weeks longer. A relapse is said not to occur.[1]

Busch, of Bonn, divides the tense fascia after having raised a skin flap on the palmar surface of the hand; the flap is then replaced and sutured. For some days the finger is left free, but when the wound granulates a cylinder of wood is placed in the palm for a few days, and after this the finger is extended by a dorsal splint.]

Wry-Neck.

Torticollis, or wry-neck, is a not very uncommon distortion of the head and neck, originating, like club-foot, from a variety of influences; some acting through the muscles—congenital, spasmodic, paralytic; others acting through the ligaments and bones—rheumatic and strumous. Occasionally the point of departure of a case is strumous affection of the lymphatic glands, and sometimes loss of textures from sloughing after burns or a gunshot wound.

Fig. 725.



Wry-neck from spastic contraction of sterno-cleido-mastoid muscle.

Congenital wry-neck.—This is the most common form of wry-neck. It is perceived a few months or more after birth, and, when suffered to proceed unchecked, gradually increases during childhood, adolescence, and adult life, until it attains the proportions of a formidable deformity. Many cases of wry-neck, reputed to be congenital, have appeared to originate from accidents at birth, in consequence of breech presentation, turning, etc. We will describe an adult case, in which the right sterno-cleido-mastoid is the head and front of the offending, for it is probable that other muscles are always either primarily or secondarily involved. The entire head leans to the right side and slightly forwards, the right side of the neck is somewhat hollowed, whilst the left side is unnaturally convex, and the patient not unfrequently complains of pain in this situation. These changes in the form of the neck are more pronounced at the upper part, *i. e.*, opposite to the base of the cranium, that being the region most influenced by the contracted muscles. The chin is drawn to one side and approaches the left shoulder; the right ear is approximated to the sternal extremity of the clavicle. The sterno-cleido-mastoid muscle of the affected side (right) has lost its symmetry, being reduced to a comparatively narrow, hard,

---

[[1] Lancet, June 9, 1877, p. 838; also Dupuytren's Finger Contraction, by Otto W. Madelung, published by G. P. Putnam's Sons; also Berl. Klin. Woch., No. 15, 1875.]

tight cord, three inches in length, the muscle of the opposite side measuring five and a half inches. This prominent cord is double below, representing the double origin of the muscle. In the adult a marked upward bend of the clavicle is often seen where the clavicular portion of the contracted muscle arises, induced by the constant abnormal traction to which the bone has been subjected, and the inferior portion of the muscle itself appears of cartilaginous or osseous hardness, and is lost in a large bony process on the protuberant clavicle. If we examine the neck and shoulders posteriorly, we observe that the cervical vertebræ have yielded to the dragging of the contracted muscle; this part of the vertebral column presenting a convexity on the left side, which is compensated for by a curvature in the opposite direction lower down. The right side of the head, neck, and right shoulder are considerably smaller than the parts on the opposite side; the right shoulder and scapula being unduly raised. A singular effect upon the face results from this difference in size, combined with the impediment to the function, which the abnormal position of the head involves. In the adult case from which we describe, so great is the difference in size between the two sides of the face, that on the right side the external canthus of the eye is distant from the external angle of the mouth three inches, whilst on the left the distance amounts to three and a half inches. The inclination of the head to the right causes the right eye to be habitually situated on a still lower plane than would be the case if atrophy of the affected side were alone operative. The atrophy and the slight bending forwards of the head interfere with the direction and use of the right eye, and cause a peculiar expression of archness and sense of difficulty and suffering. These features of the deformity are, as already mentioned, proportionally less marked in early life.

The principal muscles of the neck are probably involved, the trapezius and scaleni, as well as the sterno-mastoid. In this and other respects congenital wry-neck offers much analogy to congenital club-foot. The principal contraction affects in both cases muscles which pass over more than one articulation, the sterno-cleido-mastoid in one case, the gastrocnemius in the other; hence in the neck the mischief of morbid contraction may effect a higher degree of deformity than if the contracted muscle influenced one articulation only; in the leg the contracted gastrocnemius does not always limit its evil influence to the foot, but may contract and distort the knee. In both wry-neck and club-foot other muscles participate in the deformity; but the range of influence of those being less, or being counteracted by antagonistic powers, their contraction is not so apparent. It is an interesting question of physiological pathology, whether there is anything special in the anatomy and function of the sterno-mastoid and gastrocnemius, that they should obtain the distinction of entering into so large a proportion of cases of congenital and acquired deformity. The gastrocnemius, by its great development, its greater nervous supply, and its relation to the upright stature and locomotion of man, is certainly entitled to a peculiar and elevated rank in comparative and human myology; so, when we reflect upon the size of the sterno-cleido-mastoid, its relation to the large vessels of the head and neck, its deriving its nerve-power mainly from a special nerve (spinal accessory), and remember the influence of this muscle upon the act of respiration, we cannot deny it a pre-eminent function amongst its neighboring muscles.

We have elsewhere shown[1] that not unfrequently wry-neck appears to result from straining or injury to the neck during difficult labor, from traction of the head by instruments. It is superfluous, after what we have said of the causes of congenital club-foot, p. 333, to refute in detail the theory which would attribute wry-neck, like club-foot, to accidental uterine or pelvic pressure. Congenital wry-neck clearly originates from causes acting through the nervous system.

Treatment.—It is probable that, as with slight congenital club-foot, so slight cases of congenital wry-neck, if early detected, are removable by frictions, manipulations, and subsequent education; but all the cases we have seen, varying in age from four to forty-five years, have exhibited so much contraction and proportional secondary deformity, that we have in no case delayed division of the sterno-cleido-mastoid. It has always seemed justifiable to gain at once, by means of this operation, a large measure of relief; thus affording an encouraging starting-point for the after-labors of the attendant in overcoming the shortening of the integuments, platysma, fasciæ, associated muscles, and ligaments on the hollow side of the neck, and, in this way, gradually acting upon the altered relation of the articular facets of the inclined vertebræ.

Division of the sterno-cleido-mastoid is performed subcutaneously, upon the principles practised by Stromeyer in division of the tendo Achillis, viz., effecting the division by the smallest possible wound in the integuments and the narrowest tract through the subcutaneous tissues, and avoiding any external bleeding or extravasation of blood into the areolar tissue, or admission of air into it. Neglect of these precautions would be calculated to excite suppuration and prevent immediate healing of the puncture, and delay untowardly the employment of the necessary after-treatment, until, perhaps, the severed tendon might be reunited and implicated in the surrounding adhesions, the case thus becoming less amenable to the necessary mechanical treatment than before operation. The spot chosen for the operation should be that at which the tendon springs rigidly across the important subjacent organs, and where consequently most space is afforded for introduction of the tenotome beneath the tendon without risk to those organs. In wry-neck this spot will be found from a half to one inch above the clavicle. It is also more easy to sever the muscle entirely by keeping at this distance from the bone. In some cases we have found the sternal portion only developed and rigidly contracted; a few weak fibres attached to the clavicle having, before the knife reached them, yielded to the tension maintained by the assistant. In cases in which the clavicular origin of the muscle is broad, it is safer to divide the sternal and clavicular portions each by a separate puncture, rather than to pass the knife by one puncture made in front of the neck as far back as may be necessary to reach the whole of the clavicular portion. This precaution is justified by the anterior and posterior edges of the muscle not being on a plane surface; for although the fasciæ of the lower part of the neck may usually bind down sufficiently the vessels and nerves, and so keep them out of danger, it is well to remember the liability of meeting with abnormal distribution. The complete division is accompanied by a very sensible crack, and the head at once assumes a much improved condition. We have measured immediately after operation, and have found the difference in length between the affected and sound muscle reduced more than one-half. The puncture should at once be covered with a compress of lint, and a common bandage be applied. We have found no harm result in the case of the sterno-cleido-mastoid in allowing the ends to separate as far as they were inclined to yield. In young and flexible subjects, we have found adhesive plaster and a common roller-bandage an amply sufficient mechanical contrivance to aid in rectification of the head. Apply a long strip of adhesive plaster around the forehead and occiput, its maintenance in position being better secured by a bandage passed over the vertex and beneath the chin, the two being pinned together where the one passes over the other, above the ears. Next attach around the waist a broader band of adhesive plaster, not so tight as to interfere with the movements of the ribs; over this a turn or two of calico roller-bandage; the two should be fastened together by a stitch here and there. The surgeon has now two circular bandages, the one around the forehead, the other around the waist, which are not likely to slip if properly applied. He should then sew a strip of ribbon to the head bandage directly above the ear of the unaffected side, and carry it diagonally across the trunk to the opposite side of the waist bandage, and there pin it. By this means the left mastoid process (we are speaking of wry-neck caused by contraction of the right sterno-mastoid) will be drawn towards the right sterno-clavicular articulation, the original wry-neck be removed, and the chin brought to the median line, or in young and flexible subjects even across it, towards the affected side, constituting a temporary wry-neck in the opposite direction. The circular or ovoid form of the cranium renders it difficult to act upon it for any length of time by any apparatus hitherto invented. The apparatus will shift its direction, or rather the head will partially disengage itself. Hence even a greater necessity for manipulations exists in wry-neck than in other deformities. No apparatus effects so beneficial and lasting an impression upon the distortion as the hands of the surgeon or attendant. Whilst one holds down the shoulders, the other, standing or sitting behind the patient, should apply firmly his flat hands to the sides of the head, and direct the chin, vertex, or occiput in the required directions. The patient should be placed on a lower seat. Such manipulations need to be done with due caution and technical skill. It is not necessary to cause pain in order to produce much good. They should be employed three times a day. The plaster and roller-bandage which we have described is most convenient in reference to these manipulations. It may be unpinned in a moment, and as quickly readjusted. We have cured many cases by the means here enumerated, in periods varying from one to three months, and have never had occasion to repeat the operation. Manipulations as a precaution against relapse may be longer resorted to; but the patient's voluntary efforts are more employed, for obvious reasons, and are more successful, than in some other congenital deformities. An apparatus similar to that described at p. 360, for rectification of the position of the head in deformity from vertebral disease, may be employed in cases of adult congenital wry-neck during some portion of every twenty-four hours. It readily effects re-position of the lateral or forward inclination of the head, but is powerless to affect the abnormal rotation of the head round the horizontal axis.

---

[1] Trans. Obstet. Soc., 1862.

Acquired or non-congenital spasmodic wry-neck.—We have seen several cases of active, violent spasm of the sterno-mastoid in both sexes, oftenest in unmarried females of middle and advanced age, causing severe wry-neck. The spasm is commonly jerking, irregular, convulsive, never ceasing entirely whilst the patient is awake. The disorder has usually commenced about the age of thirty, in subjects not obviously hysterical, persons of excellent intellectual and social character, whose families have seemed prone to other cerebro-spinal affections. We have watched several of these cases for many years. The spasm and deformity have in many cases gradually increased, often rendering the patient's existence distressing, through incessant motion of the head, disturbance of sleep, and pain in the neck, apparently due to strain of ligaments and nerve disturbance, and sometimes accompanied with pain referred to the upper part of the spinal cord itself, as in some cases of "spinal irritation." Now and then the spasm is so considerable that the ear of the affected side is drawn down by a series of jerks so as almost to touch the clavicle. The patient's voluntary efforts to arrest the pulling down of the head appear to increase the disorder. Sometimes the coexistent affection of the trapezius draws the head at the same time backwards, and prevents the chin approaching the sternum. In inveterate cases, such as have existed many years, we have employed mineral and vegetable tonics, galvanism, and electricity, with only temporary benefit. However, as might be expected, generous diet, hygiene, and freedom from mental disturbance, alleviate the symptoms. Complete relief is afforded by subcutaneous tenotomy of the affected sterno-mastoid; but even this measure is only useful for a time; for after two or three months, or as soon as reunion of the severed part is complete, the spasmodic shortening and jerking return. Stromeyer had a patient who submitted to two repetitions of tenotomy for the sake of the temporary relief afforded by the operation. The author once operated on an elderly female who had suffered from spasmodic wry-neck upwards of twenty-five years. She had been unable for many years to sleep in the recumbent position, but dozed in a high-backed nurse's-chair, provided with side-supports for the head. For a few nights after the operation she slept soundly in bed. The malady, however, returned, and she ultimately sank exhausted, want of sleep appearing to be a principal cause of the fatal result. The operation on the sterno-mastoid is insufficient to affect the remaining muscles, which are sometimes involved.

In two recent cases of this affection, such for example as have existed less than two years, we cured the patients in a few months, using bromide of potassium. In others the use of the perchloride of mercury has had the most satisfactory effect. In every case which the author has cured, using internal remedies, the value of attention to the primæ viæ has been apparent. For this purpose, half a grain of the ext. aloes barbad. every night has been used. It is not improbable that the utility of hydr. perchlorid. and of argent. nitr., in these and analogous cases, is due to their stimulant action upon the hepatic and alimentary mucous surfaces, rather than upon any direct specific action upon the nerve-tissue serving the implicated muscles. Relapse is not uncommon after every mode of treatment.

An interesting instance of almost perfect cure of an inveterate case in which mere section of the sterno-cleido-mastoid had proved only temporarily beneficial, is fully recorded by Mr. Campbell de Morgan in the British and Foreign Medico-Chirurgical Review, July, 1866. The successful operation consisted in division of the external branch of the spinal accessory and the removal of a piece of the nerve, about a quarter of an inch in length. The patient was seen some two years afterwards with only faint traces of the disorder.

[Mr. De Morgan has since performed a second operation, but without relieving the patient.[1] Mr. Rivington,[2] however, was successful in curing a spasmodic torticollis by resection of the accessorius, as was also Mr. Annandale,[3] after having failed to cure the patient by stretching the nerve. The cure had remained permanent a year later.

Tage Hansen[4] reports two successful cases cured by nerve stretching. In one the head was turned to the left 100 times a minute, and this had continued four years. An incision was made along the posterior edge of the sterno-mastoid, and the nerve stretched in both directions. The contraction reappeared, as the patient was coming out of the anæsthetic, but disappeared shortly afterwards and did not return.]

Paralytic wry-neck is rare; we have not seen more than three cases. The head

[[1] Lancet, Aug. 3, 1867.]

[[2] Brit. Med. Journal, Feb. 8, 1879, p. 212.]

[[3] Lancet, i., 1879, p. 555.]

[[4] Hospitals Tidende, 2 R. v., No. 45, 1878, p. 705.]

is drawn to one side by the healthy muscle, which is deprived of its antagonist. Sometimes a case occurs in which, in consequence of difficult birth, the head falls helplessly to one side more than is common to new-born infants, probably from mechanical injury to some of the structures in the neck. Such cases resemble wry-neck from paralysis, but differ by the history, and by the evil being less confined to the sterno-mastoid. These weak necks from injury at birth, as far as we have had the opportunity of watching, have gradually recovered. In paralytic wry-neck, when the stage for ordinary treatment of the partial paralysis has passed, we can do no more than support the head by the padded-leather or steel-spring cravat. Except when the unparalyzed sterno-mastoid is structurally degenerated or very rigidly contracted, and is insusceptible of elongation by manipulations or mechanical treatment, it would be as irrational to employ tenotomy as it is in a case of contracted gastrocnemius, which has simply lost its antagonist, and which can be relieved by a suitable mechanical support without operation.

[In a number of non-congenital forms of torticollis, the head is twisted by other muscles than the sterno-mastoid. In some a nervous causation seems probable. The sterno-cleido-mastoid and trapezius muscles are supplied by the spinal accessory, and spasm of these muscles is not uncommonly a cause of wry-neck.

Sometimes the sterno-mastoid muscle is not affected, and a variety which has been termed posterior torticollis occurs, where the muscles attached to the back of the head alone are affected. The spasm may be acute or chronic, lasting for years; tonic or clonic. Various causes are assigned, such as local muscular fatigue, overwork, etc.; in other cases, however, the affection cannot be explained in this way, or on the assumption of a hysterical temperament.

Sometimes the affection is of a mild form, and disappears without treatment, or with medicinal treatment, but frequently it is extremely obstinate, and a variety of means are employed unsuccessfully. Of those recommended the following may be mentioned: Belladonna ointment, injection of sulphate of atropia, counter-irritation, ether-spray, the actual cautery, faradization, or the application of galvanism, or a mixture of both, and massage.

M. Delore has reported great success in treating a number of chronic cases of posterior torticollis, by forcible straightening under an anæsthetic, and fixation by a permanent bandage (silicate of potash strengthened by pasteboard) applied around the head and trunk, and worn for weeks or months.

M. Delore has found that wry-neck, due to a permanent contraction of the posterior muscles, is not so infrequent as has been supposed, and that it may result from a variety of causes.

The attitude may resemble that caused by a contraction of the sterno-mastoid, but in the cases of a pure type this muscle is relaxed, and hence tenotomy or myotomy is not indicated. His method of operating consists in anæsthetizing the patient and grasping the head firmly with both hands; assistants hold the shoulders. The deformity is gradually corrected, and at times the sense of tearing fibrous tissues is felt. After the head is in position, a silicate of potash bandage is applied about the head, neck, shoulders, and trunk, leaving the face and arms free. The bandage is worn a month, and sometimes in severe cases it has to be renewed. In thirteen cases, some of them of deformity of a severe and persistent type, complete success was obtained without relapse.

This method has certain advantages, which are manifest in watching a case so treated. The muscles in a state of spasm are kept more perfectly fixed than is possible by any other apparatus which can be devised, and hence the muscles are not irritated by more or less intermittent strain.

Instead of silicate of potash, plaster-of-Paris bandages have been used by Dr. A. T. Cabot, of Boston, as they harden much more quickly than liquid-glass bandages. The appliance is, however, much more clumsy. Instead of stiffening the bandage by pasteboard, the writer has been able to give sufficient firmness to the bandage, while hardening, by incorporating light strips of iron.

In certain milder cases of posterior torticollis it is evident that it is desirable not only to use force to rectify the position of the head, but, as a help toward this, to support the chin by apparatus, as the weight of the head and its tendency to fall forward is a source of irritation to the muscles implicated in the causing the deformity.[1]]

Wry-neck from disease of the cervical vertebræ is caused by strumous, and some-

times by rheumatico-strumous disease of one or more cervical vertebræ, from which the head inclines to the affected side. The chin is directed to one side, although this feature is less marked than the sideward falling of the head. In bulging of the opposite side of the neck, and in general appearance, these cases much resemble congenital wry-neck, but are distinguished from it by their history, the pain on motion, the aspect of strumous or constitutional disorder, by hectic, by the instinctive aversion of the patient to the surgeon's handling of the head, and concomitant glandular or other forms of strumous disorder in the one case, or rheumatic affection in the other. The pathological changes common to disease of the vertebræ in each region, and its peculiar dangers when situated in the neck, are described in a previous essay. Great caution is necessary in handling these cases, lest the disintegrating bones give way suddenly to the pressure, or the reparative process which may be going on be interrupted. Much benefit to the disease itself, and gradual improvement in the position of the head and neck, may be effected by a well-adjusted supporting and rectifying apparatus, as well as by the recognized medicinal, dietetic, and hygienic treatment of the constitutional malady. We have twice witnessed death as sudden as in apoplexy, in cases in which suitable support of the head had been neglected, and the patients had persisted in maintaining the erect position, having walked about supporting their heads with the hands. The most efficient apparatus consists of a padded metal plate, secured by straps beneath the axilla and around the chest upon the shoulder of the side to which the head inclines. From this shoulder-pad an iron upright piece extends upwards, by the side of the neck, to the parietal region. The lower end of this upright is attached to, and moves upon, the shoulder-plate by means of an endless ratchet-screw; the upper end is connected with a pad intended to be adjusted and pressed against the parietal region. In adults and very severe cases, this apparatus may be attached to a common spinal support for the chest and pelvis, for the sake of greater fixity and more powerful leverage. Sometimes an iron stem is required to extend upwards on one or both sides of the head, with connecting straps to be applied beneath the chin and occiput, so as to receive the weight of the head. Much opportunity for the ingenuity of the instrument-makers is afforded by these cases. In the present day we do not commonly find it necessary to employ the cumbrous and unsightly machines, consisting of an iron scaffold and gibbet for suspension of the head, to which surgeons resorted as lately as the commencement of the present century.[1]

[1] [Consult also, Kormann, Schmidt's Jahrbüch., Bd. 179, 1878; Swan, Dublin Journ. Med. Sc., Aug., 1879, p. 117; Torticollis ar-

Knock-knee, In-knee (*Genu Valgum*).

[No subject in orthopædic surgery has, within the last few years, attracted such attention as the treatment of genu valgum; and the recent literature on the subject is copious.

The anatomical researches of Mikulicz[1] show that deformity is not due to an abnormal condition of the ligaments, but to an unnatural shape of the bone, which causes a downward projection of the internal condyle. This is the result partly of a curve in the diaphysis, but partly to an unequal growth of the two sides of the diaphysis near the epiphyseal line. The epiphysis itself in pure genu valgum not the result of arthritis is not altered in shape. Contraction of the outer hamstring is not at present regarded as necessarily present; it has been found absent in many cases, and is not, therefore, in a causative relation with the deformity.

Ollier's experiments have shown that an irritation of the internal condyle could cause a hypertrophy of this part; but though this undoubtedly may cause deformities resembling the ordinary knock-knee, this latter must be considered as not the result of inflammatory changes in the bone, but probably the effect on the growth of bone of abnormally distributed weight. Tripier, Verneuil, and Guéniot agree with Mikulicz, that the deformity is due to an abnormal shape of the femur at the knee-joint, but believe that the change is in the internal condyle itself, which is abnormally lengthened.[2]

Mr. Brodhurst does not regard the lengthening of the condyle as the cause of the deformity; but in this he is at variance with all surgeons who have recently studied the question.[3]]

This frequent deformity, of which instances are met with at all ages, consists of an inward yielding of the knee-joint, in consequence of weakness of the ligaments and muscles which respectively connect or surround the articular extremities of the femur and tibia. Its causes are identical with those which produce in-ankle or flat-foot (talipes valgus spurius), p. 351.

Abnormal states of general nutrition in children and adolescents, dependent upon insufficiency or improper quality of food, are a common predisposing cause of this deformity. Sometimes it appears probable that the constitutional weakness, or laxity of tissue, has been engendered less by unsuitable supply or quality of food than by imperfect assimilation, owing to deficient aëration of the blood, as in children reared in confined dwellings, both in town and country. In many cases, the abnormal nutrition proceeds to the length of developing an unmistakable rachitic condition, known by the coexistence of the peculiar curvatures of bones which characterize that disease. Our observation of the numerous gradations of knock-knee met with in young children, varying in outward appearance from the most flourishing health to the most miserable, wasted, and dwarfed extreme rickets, has convinced us that even in the slighter forms of knock-knee a degree of impaired assimilation of food and an abnormal state of blood, similar to that present in rachitis, exists. In these slighter cases of knock-knee, traces of rachitis will be found in prominence and deformity of the cartilages of the ribs, flattening of the sides of the chest, and sinking-in of the sternum. One or more severe attacks of bronchitis, or broncho-pneumonia, have frequently been with justice regarded by the friends as the forerunner of the "weakness of the limbs." In many instances the earliest link in the chain of causation has been an error in the infant's diet; namely, the substitution, for an insufficient supply of breast-milk, of farinacea boiled in *water*, with the addition of little, if any, cow's milk. Sometimes we may ascend a degree higher, and discover an hereditary pathogenetical influence. We have several times observed knock-knee in small, delicate, prematurely-born children; the limbs, as a consequence of general weakness, having yielded to the superincumbent weight of the trunk. Such cases should not be confounded with the *inverted* flexed and contracted knees which occur in children who, in consequence of premature birth, have suffered from asphyxia neonatorum (p. 349). Knock-knee often shows itself before the child has attempted to walk, this act being occasionally delayed by it as much as three or four years. When the deformity attains a certain grade, it may increase rapidly from the effects of walking, or it may increase so gradually as not to excite the parent's anxiety, until at length, about the age of seven, ten, or twelve years, the child is again "thrown off the feet," and

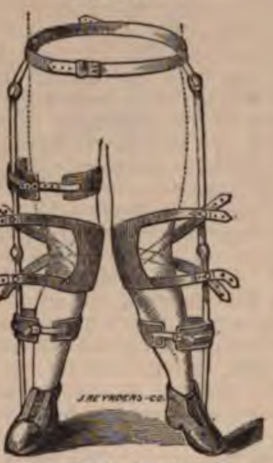
[[3] Chiari, Wiener Med. Woch., Sept. 7, 1878; Farabeuf, Peyrot, Gaz. des Hôp., Jan. 6, 1880.]

becomes incapable of walking without crutches or other support. The deformity often takes place in tall, rapidly-growing lads from the age of twelve to eighteen, who may have exhibited no previous tendency to it. Undue exercise, and fatigue in standing and walking, with late hours and the poisoned atmosphere of ill-ventilated places of business and dormitories, appear in such individuals to have contributed to the complaint. Undue strain upon a sound limb, in consequence of some other defect in the opposite limb throwing increased exertion and weight upon it, may produce this deformity.

[The treatment of knock-knee at present in vogue is, 1, gradual straightening, until the limb has assumed a shape approaching the normal one; 2, forcible straightening, according to the method of M. Delore; 3, osteotomy.

Gradual straightening is brought about by orthopædic apparatus, or, as has been recently suggested by German surgeons, the frequent application of plaster bandages with the limb brought straighter at each application.[1] Delore's method consists of forcible straightening under an anæsthetic. This is brought about by a separation of the epiphysis from the diaphysis, and in certain cases probably by rupture of the external lateral ligaments. In children this latter accident is not liable to occur. When it does occur recovery is delayed, and orthopædic apparatus will be probably needed as a support in locomotion for a time.

Fig. 730.



Apparatus for knock-knee.

As an aid in fracturing, an osteoclast has been used, or mechanical means to increase the amount of force used.

The method of forcible straightening after section of the external lateral ligament is one which should be discarded, as better means are now at the disposal of surgeons. Langenbeck, who previously advocated and practised the procedure, reports that it is almost impossible to prevent the entrance of air into the joint, a risk which is not incurred by other methods.[1]

Forcible straightening has, in the hands of Delore, Tillaux, and Duplay, brought about good results; in certain cases, however, the results have been unsatisfactory; in a few inflammation of the knee-joint followed, and a death has been reported.[2]

Osteotomy, in treating the deformity of knock-knee, has, within the last few years, been performed by German and English surgeons a great number of times, with reported remarkable success.

The method of Meyer, Billroth, and Schede of straightening the limb by section of the tibia has met with disfavor, as the internal condyle is in this way disregarded. Mr. Ogston, to remove this deformity, sawed off the internal condyle with an Adams saw, completely severing the internal condyle from the femur. Mr. Reeves has substituted the chisel in place of the saw, driving the former nearly into the joint, and completing the separation by a fracture which occurs on straightening the limb. In both these procedures the internal condyle is forced up. MacEwen and Chiene have made a wedge-shaped opening across the internal condyle by severing the femur from the inside, using chisels of different thicknesses, the largest being used first; the limb is then straightened forcibly. In some cases, MacEwen has found it necessary to chisel the tibia also. MacCormac entered the chisel on the outer side of the femur just above the line of the epiphysis; the chisel is driven nearly through the femur, the limb is then straightened, and the uncut part of the femur broken. A wedge-shaped gap is left on the outer side, which fills with granulations. Taylor and Barwell divided the femur above the knee-joint, Mr. Barwell chiselling also the tibia a short time afterwards. The joint is opened in Ogston and Reeves's operation; in the others it is probably not touched. In successful cases the patients are able to walk about in from three to six weeks. Success is obtained in by far the greater number of cases, the risk of Ogston's operation being comparatively slight, judging from the few deaths out of the many hundred reported cases. Some of Mr. MacEwen's patients have been able after recovery to walk thirteen miles at a stretch, thus proving the completeness of the cure.

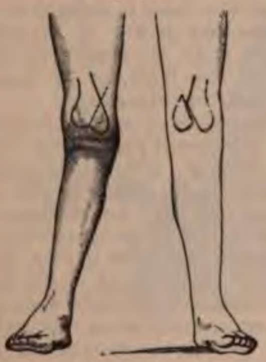
Fig. 731.



Dr. Ogston's operation for knock-knee (Bryant).

Although the number of deaths from Ogston's operation is remarkably small, yet the method of supra-condyloid osteotomy, with antiseptic precautions, offers the patient the best chances for the speediest recovery. The limb immediately after the operation should be fixed, and the most thorough fixation is given by a plaster-of-Paris bandage, with a fenestrum for the application of dressings.[1]]

Treatment of knock-knee.—We have heard it maintained, that, as a rule, children recover spontaneously from this affection. In a small proportion of cases, spontaneous recovery of good power of walking takes place; but an examination of such instances has shown us evident traces of the affection in some persistent enlargement of the internal condyles, with inability to take long walks on several successive days, without weakness and pain on the inside of the knee. Slight cases will recover under improved dietetic and hygienic influences, with the aid of suitable manipulations, and the discontinuance of prematurely teaching the child to walk. Sometimes we can, in addition, advantageously recommend the recumbent posture during certain short periods of the day, and combine with this repose the placing a soft pad between the condyles, the limbs being extended, and the ankles being gently drawn towards each other by means of a soft bandage, strap, or other ligature. In carrying out this plan, we require to watch that the knees be not too fully extended, *i. e.*, bent backwards beyond the horizontal line of the couch; a condition apt to ensue as another consequence of undue laxity of articular ligaments. In worse cases, more persistent mechanical means are requisite; simple padded wooden splints, a short one applied behind the knee to prevent flexion, and a long one reaching from the trochanter to the malleolus externus, not too tightly bandaged, may suffice. Modifications of such splints, constructed of metal or wood articulated at the knee, furnished with a ratchet-screw to permit adjustment to the inward inclination of the knee, and secured by straps and buckles, may be found at most instrument-makers. On the whole, even in moderately severe cases, but especially in aggravated cases, no apparatus is so efficient as a well-constructed iron to extend from the pelvis, on the outer side of the limb, sometimes on both sides of the limb, to the bottom of the shoe, the hip and ankle joints being left free, the knee *fixed* in a somewhat improved position, which may be further rectified from time to time, as the progress of the case demands, by means of the adjusting screw or straps. The surgeon should see that the apparatus is constructed with due regard to the anatomico-pathological and the mechanical wants of the case. For example, irons, to be promptly effective, need to take suitable points of support against the upper part of the outside of the thigh and the lower part of the outside of the fibula.

Severe cases require the knee to be prevented from bending when standing, during a period varying from three to six months; then freedom of motion during a part of each day for a similar though variable period; and, lastly, perfect freedom yet a few months, before discontinu-

ance of the support. The total average duration of bad cases in advanced childhood may occupy two years. Care should be taken to employ daily frictions and manipulations, so as to prevent the knee becoming stiff in an extended position. We were formerly accustomed, in severe in-knee of adolescents, to aid the mechanical treatment by previous section of the outer hamstring; but the observation of the length of time occupied in the treatment notwithstanding the tenotomy, and indeed a conviction forced upon us that the operation did not appreciably shorten the treatment, has caused us for many years past to discontinue recourse to it. In adolescents the most severe cases will recover with the aid of manipulations, exercises, and mechanical apparatus, without confinement to the couch; but until a straight limb is obtained, recumbency, by removing the weight of the trunk, greatly accelerates recovery. We are bound emphatically to protest against the operation of removal of a wedge-shaped piece of bone from the upper part of the tibia, performed by M. Meyer for the cure of this deformity. It is a sufficient condemnation of this severe operation to remind the reader that knock-knee is not dependent on curvature or deformity of the tibia, but upon a removable displacement of the relation of the articular extremities which enter into the knee-joint. Consequently, an operation of the kind performed away from the joint is at best a clumsy proceeding, and not without danger. Division of the external lateral ligaments, another operation recommended for knock-knee, is also unnecessary. [See p. 362.]

Occasionally the knee joint yields outwardly instead of inwardly, constituting a deformity exactly the opposite to knock-knee. We have named this affection, *Genu extrorsum curvatum*. The treatment of it should be conducted upon the same principles as that of knock-knee.

[*Curvature of Bone.*

A certain number of the curvatures of the long bones in young children correct themselves without treatment. In others the deformity increases with growth. Horst,[1] in fourteen cases under observation from four to nine years but subjected to no treatment, found that in nine cases there was an increase in the deformity, in four no increase, and in one improvement. Of cases treated by apparatus, in none did an increase of the deformity take place; in sixteen improvement was observed, the improvement being most marked when the curve was greatest and between two and three years of age. In some no improvement took place under treatment, but in these the curvature increased after apparatus was abandoned. Apparatus was worn in the successful cases from nine months to two years, and no injury to nutrition was observed from the use of the apparatus. This has also been the experience of Dr. Gibney.[1]

Where the bone is so hard as to resist the correcting power of apparatus, the deformity may be corrected either by section of the bone, or by breaking it, —osteotomy or osteoclasis.

The operation of osteotomy has won for itself a prominent place in the records of modern surgery. MacEwen has performed osteotomy on 557 limbs in 330 patients. Of these 220 were knock-knee, 64 were simple bow-leg, 40 patients with 80 limbs had anterior and other curves, 6 were patients with ankylosis (1 of the hip and 5 of the knee). Both limbs were operated on at once, and when several curves needed treatment, sections of all were made at the same time. In one case ten osteotomies were done at one sitting. These operations were not subcutaneous; the soft parts were divided down to the bone, and the chisel inserted at right angles to the axis of the bone. Strict antiseptic precautions were enforced. All the above patients except 8 recovered without suppuration. Of the 8 with suppuration, 7 recovered, after slight delay, 1 got out of bed shortly after the operation, stepped upon the limb, forced the bone through the skin, sloughing followed and amputation was performed; of those operated on, 3 died subsequently, 1 of pneumonia, 1 of diphtheria, 1 of tubercular meningitis. The others recovered with perfectly useful limbs.

Instead of removing a wedge-shaped piece of bone from the convexity of the tibia and fibula, it is a much simpler operation to divide with a chisel the fibula and tibia, and straighten the limb, leaving the wedged-shaped gap to fill up, which it appears invariably to do. The tibia should be divided at the point of its greatest curvature, and the fibula at the same level. Separate incisions should be made over the tibia and fibula, and the chisel inserted and turned so as to be at right angles with the incision made in the axis of the limb. The chisel should be $\frac{1}{2}$ to $\frac{3}{4}$ of an inch wide and should taper equally on both sides. Antiseptic precautions do not appear from the reported cases to be essential to success (Poore).

Instead of the chisel a subcutaneous saw has been used and is preferred by some surgeons. These deformities have also been corrected by fracturing the limb, by the hand or by the aid of an

Bigg's apparatus for restoring position after extension of contracted knee-joint (Erichsen).

osteoclast. The soft parts have been found to stand without injury a great deal of pressure, sufficient in the majority of cases to break bone. Immediately after the fracture the limb should be held in the corrected position by means of loops of bandage pulling in different directions and held by assistants, who should hold the limb also by the toes and knee. A bandage should be applied smoothly, cotton placed over the parts least covered with soft tissues, and plaster-of-Paris bandages applied. Swelling does not occur if the bandage is well applied, and no further treatment is needed until union takes place.

The danger from this procedure appears to be very slight. At an autopsy in a case reported by Dr. A. T. Cabot, where death took place from tubercular meningitis some time after osteotomy, it was found that fracture had occurred without splintering, and firm union had occurred without deformity.[1]]

On Orthopædic Operations applicable to the Removal of Curvature of Bones.

Under the section on Rachitis in this work the value of mechanical treatment

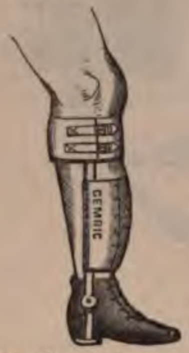
of curvature of the long bones of the lower extremities will find appropriate mention. In very early childhood, whilst the curved bones are still in the softened stage, the straightening of them with the aid of splints, strapped or bandaged on the parts, may, when the treatment is conducted with gentleness and patience, be successfully accomplished, or "irons" may be substituted for splints. The bent rachitic bones of the forearm may also, in the early stage of the disorder, be straightened by splints or with the help of spring instruments. So also the long bones of the lower extremities in adolescents affected with the singular and pathologically speaking little understood disease variously denominated "mollities ossium, osteomalacia, rachitismus adultorum," may be easily straightened by mechanical means.

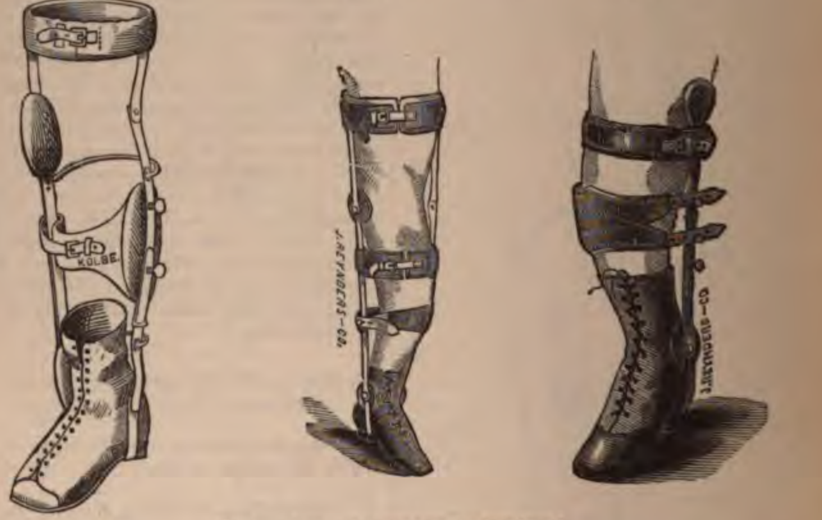
[Fig. 734.



Bigg's apparatus for anterior curvature of leg.]

It is different when, in ordinary rachitis, the bones have reached the stage of normal induration or "eburnation." On such bones mechanical pressure makes no perceptible impression. In the adult, therefore, affected for instance with tibia and fibula of ivory hardness, and bent to an angle of 75° or 80°, the limbs being shortened several inches, the act of walking being laborious and painful, owing to the consequent and undue strain upon the ankles and knees, which become effected with genu valgum and talipes valgus spurius or flat-foot, the question has arisen whether such an individual, insusceptible of help from irons, shall be left incurably lame.

[Fig. 735. Fig. 736. Fig. 737.



Various forms of appliances for bow-legs.]

A case of this nature was submitted for my opinion by Mr. L. Stromeyer Little. The case was that of a young adult female, otherwise in good health, and free from deformity in the upper half of the frame. It was agreed that relief might be obtainable from removal of wedges of bone from the tibia and fibula, and subsequently placing them in the straight position, and their treatment after the manner of accidental compound fracture. The difficulty in deciding on the propriety of such an operation resulted from the uncertainty whether bones thoroughly "eburnated" after rachitis could, when severed surgically, for the cure of distortion, be confidently expected to reunite after the manner of an ordinary compound fracture of healthy bone. No known facts bearing on this point, such as the history of a fractured rachitic "eburnated" bone and its reparation, were available to help the decision. After reflection upon the manner in which reparation is effected after fracture of a healthy bone, it was decided that reunion of the artificially divided eburnated bones would take place. The operations took place at the National Orthopædic Hospital. The tibia and fibula of each leg were severed and wedge-shaped pieces removed, the periosteum having been scrupulously respected as much as possible.

The operations presented no unexpected difficulties. They were arduous, owing to the depth at which great part of the sawing had to be accomplished, and the blunting effect of the hardened and enlarged bones upon the best tools. The leg first operated on did not heal without the supervention of two moderate abscesses, and the throwing off of small necrosed particles. The health did not suffer. After six months the patient left the hospital with one straight limb, the inversion of knee and flat-foot having been simultaneously overcome. She returned to the hospital after six months' absence and requested to have the second limb operated on. The experience acquired by the first operation was not lost upon the second. This time she made a more speedy recovery and had no abscess. A year and a half after the first operation she walked with the help of a stick, having two straight limbs.

Mr. Little operated on an analogous case of bony curvature in the upper extremity. A boy suffered from inability to pronate the forearm, owing to the bones having become deformed during infancy from softness and irregular muscular contraction. The forearm was constantly fixed in a state of supination, diagnosed to result from the unduly arched radius being locked in its movements by contact with the ulna. Section of the radius, placing it in a normal position, and healing of the artificial compound "solution of continuity," resulted in a few weeks without any disturbing symptom and with the desired beneficial result.

These operations, fairly indicated and eminently successful, offer an encouraging page to the orthopædic surgery of bones. As in other departments of orthopædy, it may be hoped that increased attention to such deformities in their early stages may render the opportunity of important surgical interference less frequent than we have witnessed.

Ankylosis of the Knee and other Articulations.

The successful labors of orthopædic practitioners have contributed to improve the knowledge of the real condition of joints after the cessation of various forms and degrees of inflammation and degeneration. The erroneous notion, that long-continued repose of a joint alone sufficed to induce such alterations in its articular surfaces as to lead to bony union, and the remarkable rigidity and immobility which result from the agglutinated or contracted extra-articular structures—fasciæ, muscles, and ligaments—especially when dense, fibrous, deeply-extending cicatrices coexist, favored the supposition of the common prevalence of true bony, irremediable ankylosis. We know that absolute bony union of articular surfaces is a comparative rarity, even in pathological cabinets.

For practical purposes we may divide the conditions in which joints contracted from disease are presented to the surgeon, with a view to the restoration of form and motion, into three classes. 1st. Those in which the resistance to motion is furnished solely or mainly by the extra-articular tissues. 2d. Those in which, in addition, more or less considerable changes within the articulation have occurred, viz., transformation of the synovial surfaces, vascular adhesions, fibrous adhesions, erosion of cartilage or of bone, mineral or bony deposits. 3d. Absolute osseous ankylosis.

The first class of cases is common. We have met with numerous instances of knee and elbow-joint contractions, induced respectively by severe, deeply-extending burns, by phlegmonous erysipelas, by "swelled leg," in which the history of the case, the state of obvious contraction and adhesion of the extra-articular tissues, together with the absence of displacement or deformity of the articular extremities of the bones, left no doubt in our minds that the articular surfaces, notwithstanding the paucity of motion, or its entire absence, were free from organic change. In these cases, restoration of form, and often an almost complete recovery of spontaneous, *i. e.*, voluntary, movement, may be effected without difficulty.

The second class of cases includes some which have had a similar origin to those of the first category, but in which the injury or inflammation has extended to the interior of the joint, or at least has involved the capsular ligament. In these cases, deep, retracted, indented cicatrices, and bands of indurated adventitious tissue, penetrating, it may be presumed, into the hollows and sinuosities of the ends of the bones, even if all happen to be exterior to the articulation, tell of exposure of the synovial membrane so near to the disease, that it is improbable that it will have escaped. These cases admit of rectification of position, and commonly some degree of voluntary motion follows, but not always until months or years after active orthopædic treatment has been discontinued. The bulk of the second class consists of cases resulting from strumous synovitis (?) and diseases of the articular extremities, rheumatic and gouty contractions, and distortions from accidental violence.

The strumous distortions of the knee usually present considerable mobility within a limited range, with much deformity and prominence of the internal condyle from subluxation, and from wasting of the member above and below the articulation. They are usually straightened without difficulty, although much prominence of the condyles and subluxation will remain. Partial mobility is usually recovered.

The rheumatic cases which apply for orthopædic relief are principally of two kinds, those in which "chronic rheumatic arthritis" subsists, and those rarer instances of acute articular inflammation excited by exposure to cold during gonorrhœa, childbed, or an early stage of lactation. In the first kind, during the comparatively early stage, much intra-articular fluid secretion and free mobility within a certain range remain. At a later stage, in proportion to the development of gelatinous and vascular adhesions and mineral deposit, the movement becomes more limited. Before and subsequently to the appearance of Bonnet's work, Thérapeutique des Maladies Articulaires, we have been accustomed to attempt, by gentle manipulations and gentle but firm employment of mechanical contrivances, to restore these limbs to greater usefulness as regards movement and symmetry. We have succeeded in obtaining the latter, but not the former desideratum. In fact, as might be inferred from correct pathological knowledge, the benefit of orthopædic treatment is in the inverse proportion to the anatomical degeneration which the rheumatic joint has undergone.

In the second kind of rheumatic cases of partial ankylosis, those which have commenced with very acute affection of one joint, most often the knee, the loss of motion occurs rapidly, and is frequently complete. It seems, in these cases, that an acute destruction of the synovial surface, with rapid exudation of mortar-like plastic material, takes place, causing firm agglutination of the ends of the bones.

Tact in the examination will usually show that absolute immobility of the knee, from whatever cause the ankylosis has proceeded, does not exist. The surgeon can with certainty determine that the joint is movable if an energetic effort to bend or straighten the limb produces a sharp pain through it. We may deduce some favorable conclusions as to the state of the joint if we find the patella movable. This bone may sometimes be moved upon its perpendicular axis when no motion is perceived upon the horizontal one, and when no flexion or extension of the knee can be effected by ordinary handling of the joint.

We make no other mention of stiffness of joints from common articular rheumatism, acute and chronic, than to observe, that as this affection usually leaves the synovial membrane intact, no deformity, as a rule, remains, the exception being the ankle; here the weight of the body comes more mischievously into play than elsewhere, and sometimes gives rise to a rheumatic in-ankle or flat-foot.

Many rheumatic contractions, those which are the least amenable to treatment, belong to the peculiar form of the disease denominated "chronic rheumatic arthritis" by Adams, of Dublin, the "rheumatoid arthritis" of Garrod.

As a rule, in reference to orthopædic treatment, a correct judgment of the condition of a joint contracted from disease may be formed from the history and the external appearance, aided by careful manual examination. In the hip, the diagnosis is sometimes more difficult, because the history communicated may be fallacious, in consequence of the greater liability to errors in diagnosis during the first stage of disorder in and around this articulation. Thus we have seen hip-contractions in which the primary hip-affection had been originally sciatica, muscular, and fascial rheumatism of the bulk of muscles of the hip and loin, or one of the forms of rheumatism of the joint itself, or "morbus coxæ," or the result of accident. To these causes of hip-contraction, which are not always diagnosed, we may add the peculiarly grave intra- and extra-articular exudation which occasionally occurs at the close of malignant scarlatina, and the less serious persistent drawing up of the thighs which occurs (without pyæmia) during a tedious confinement to bed from fevers and phlegmasiæ, especially in persons whose growth is not complete. We have also met with rigid hip-contraction, with pain and wasting, which had commenced during pregnancy, from uterine influences; also after childbirth, from puerperal disturbance; and in unimpregnated, as well as in unmarried women, even from great fecal accumulation in the intestines. Whilst reminding the surgeon of the various causes of persistent hip-contraction, we may complete the list by adding congenital contractions and luxations, paralytic and spasmodic contractures, some of these being hysterical, and some very grave affections, proceeding from disease of the brain or spinal cord, sometimes coexisting with angular spinal curvature. We have not enumerated these numerous causes of hip-contraction, as if they were so many pitfalls to the surgeon; but in order that, knowing what may have produced a given contraction, the young surgeon may be forearmed for diagnosis and successful treatment.

Treatment of partial and complete ankylosis.—The several forms of contracted joints of the extremities above enumerated admit of three modes of treatment: 1st. Mechanical extension, including manipulations and shampooing. 2d. Tenotomy, succeeded by gentle, gradual mechanical extension. 3d. Violent extension under the anæsthetic influence of chloroform, sometimes preceded by tenotomy.

The majority of joints affected with incomplete ankylosis, even the knee, elbow, or hip, still more the smaller articulations, and even after three or four years' duration of the contraction, admit of as full and prompt restoration by gradual, gentle employment of mechanical extension as by either of the remaining modes of treatment above indicated, with the advantage of the treatment being conducted without pain, suffering of any kind, or confinement to the house. In severe knee-cases of many years' duration, subcutaneous division of the hamstring muscles may advantageously precede the mechanical treatment, the surgeon bearing in mind that here, as in other distortions, success depends more upon the manner in which the mechanical treatment is conducted than upon operative interference. In a small proportion of cases, those in which apparent total immobility exists, or in which it is obvious that partial calcareous deposit has taken place, violent extension, with the aid of chloroform or ether, may be employed. We annex a few detailed observations on the mode of conducting each of these processes.

Mechanical extension of partially ankylosed joints.—Long experience in the use of mechanical apparatus shows how little actual apparent power is required to overcome the most rigid contractures of joints. The first condition of success is the correct adaptation of the appropriate apparatus to the size and natural movements of the part. It is of much importance also, that, when practicable, the apparatus should only limit the movement of the affected joint towards the contracted side, *i. e.*, it should not immovably fix the part in every direction, but should leave some "play" to the limb in the direction which it is wished the part should take. No curable ankylosis, free from bony union, can resist gradual, gentle pressure; we only resort to tenotomy, in addition to mechanical extension, for the purpose of saving time. A little consideration will explain how apparently slight continued pressure can effect so great a result as the straightening of a knee contracted for twenty years from former articular disease or injury. The uninitiated surgeon is accustomed to regard such a joint as "nearly ankylosed;" perhaps he does not reflect that, if bony union have not taken place, the opposing structures are "soft parts," *i. e.*, shortened muscles, ligaments, fasciæ, cutaneous textures, and cicatrices, all liable to yield to steady pressure. It is probable that as soon as this gentle pressure is applied, the contracted muscles, shortened merely from position and repose, *not being spasmodically affected*, resist elongation, but they speedily tire, and give up the unequal struggle; the non-muscular parts, however dense they may be, probably undergo some change of vascularity, some interstitial change in their nutrition as a consequence of the *gentle violence* they undergo, through which their mechanical power of resistance is diminished. An increase of temperature and of bulk of the part undergoing mechanical extension is usually perceived, which we believe to be due to increased flow of blood consequent upon the stimulus of the state of tension in which the resisting tissues are maintained. This augmented flow of blood is unaccompanied by inflammation or even by pain when the part is at rest. Such appears to be the process in the structures on the contracted side of the member. The treatment probably receives aid from the muscles on the uncontracted side. The direction of the distortion was originally determined by the stronger set of muscles, or by those most advantageously situated, having overpowered the weaker set. When the contracted muscles yield in their turn to the mechanical instrument, the muscles situated on the uncontracted side tend to recover their lost sphere of action, and assist replacement.

The knee-joint, being a simple hinge, while the thigh and leg each offers a great length of leverage, is advantageously formed for successful orthopædic treatment by mechanical extension; and consequently we meet with no partially ankylosed knee which cannot be straightened and rendered fit for use, without the aid of tenotomy or chloroform, in a period varying from one to three months.

The anatomical relations of the hip-joint render it less favorable for orthopædic treatment than any of the ginglymoid articulations. At the hip, the shortness of the lever afforded by the small depth of the pelvis, and the difficulty of fixing the pelvis, explains why, when power is applied to the thigh with the view of extending the abnormally flexed or contracted hip, the lower part of the vertebral column, back, and loins, yield anteriorly, causing an extreme hollow in the loins (lordosis). In fact a small part only of the power employed is effective on the contracted hip-joint, the greater part being expended in dragging forwards the lowest dorsal and the lumbar vertebræ. We may mention, in illustration of the comparative difficulty of straightening the hip, that in an instance of uniform fibrous and vascular membranous adhesion of the head of the femur within the acetabulum after death, the partially ankylosed pelvis and thigh having been removed from the body, we were unable to extend the hip by any power we could exert with our hands, until the capsular ligament and some of the adhesions within the acetabulum had been severed with the knife. The same kind of adhesions in a knee would have yielded to the power fruitlessly employed at the hip.

Great ingenuity has been displayed in the manufacture of the apparatus. Occasionally considerable demands upon the skill of the mechanist are required. The continued attention of orthopædic practitioners who, during the last five-and-twenty years, have trodden in the footsteps of Scarpa and Stromeyer, bringing pathological and anatomical knowledge, with experience, to the aid of the instrument-maker, has revolutionized, simplified, and thus far perfected orthopædic apparatus. As a general rule, elaborate instruments should be avoided. They are often strictly articles of luxury, not obtainable for the treatment of the majority of cases that present themselves in private, and especially in public practice. We may affirm that when *nothing* can be effected for the relief of a deformity without a complicated instrument, very little can be effected with its assistance. Yet in numerous instances, as in congenital club-foot of adolescents, in considerable knee-contractions, and subluxation, the necessity of well fixing one part whilst another is acted upon, or the complicated character of the deformity itself, entails corresponding need of an elaborate contrivance.

Different mechanical forces are employed—the lever, the screw, and the spring; the last two often resolvable into the lever, screws and springs being employed to modify the action of the lever. The discussion of the relative advantages of the different modes of applying these forces would lead us away from our immediate object.

It should be borne in mind during the employment of these forces in orthopædic apparatus, and especially in the use of the screw, that it is available less as a means of abruptly forcing the deformed parts into their natural position than as an adjusting contrivance. In any case in which the screw is *forcibly* employed, unless for a very brief period, excoriation, sloughing, or intolerable pain, will inevitably result. In some *patient* individuals, vesication, and even superficial sloughs, may be induced over projecting bones without complaint of pain—an urgent reason for anxious examination of a part subjected to pressure, especially by the inexperienced orthopædist. Large sloughs are more than inexcusable.

Every apparatus should be padded, so as to avoid pressure upon prominent points of the bone, and adapted to each individual case. The orthopædic apparatus, like that for a fractured limb, should compress the part in its circumference as little as possible, and never tightly encircle it. It should act gradually, *in proportion as the deformity itself changes its form*. We have endeavored in our previous remarks to show, that if a contracted member,[1] a knee for example, is evenly secured in a suitable apparatus, accurately adapted to the degree of bending of the joint, the processes which ensue in the joint when a moderate tension is imparted soon favor the moving of the joint in the direction contrary to that which it may have long maintained. A contracted knee resting upon its posterior aspect in an apparatus, tends by its own weight to regain a straighter position.

At the outset, the surgeon should be content simply to apply the instrument to the deformity, and not to apply the deformity to the instrument, as is too often attempted by novices in orthopædic practice. In this gentle manner of proceeding, the first difficulty in the treatment of every case of deformity is overcome,—the patient suffers nothing from the attempt to straighten the part; the simple inconvenience of wearing an apparatus, the irksomeness attendant upon necessary confinement of the affected part in an unfamiliar instrument, is his only trouble, and one which is speedily, in a day or two, overcome. Having once applied a well-fitting instrument, the screws or straps by which it is adjusted to the now improving member require to be advanced or tightened as opportunity offers. An impatient advance of the pressure will, by production of pain, and necessity for relaxation of the instrument, occasion loss of time. The principle of action in the progress of mechanical treatment should be that of never advancing too rapidly, so as to risk the necessity of receding. By gentle means, and uniform steady advance, the patient's confidence, so essential to prompt recovery, remains undiminished. By subjecting the member to no greater pressure than can be easily borne, no temptation to loosening the apparatus is afforded to the timid, and no risk is incurred of occasioning excoriation or inflammation in individuals possessing greater endurance, or in young children, whose cries may be attributed to other causes. In this manner, in suitable cases, the opposition offered to restoration by fasciæ, tendons, ligaments, and ill direction of articular surfaces, apparently irresistible, may, with the further aid of manipulations, be removed.

---

[1] The greater number of contracted joints, when not affected with bony ankylosis, if left to themselves, may be regarded as contracting joints; for the contracting process is ever progressing until it attains the maximum.

In the choice of mechanical apparatus the surgeon should also be guided by that principle which actuates him in the selection of therapeutic agents in any internal or external disease, viz., the use of that means the action of which he best understands, or in the use of which he has had most experience. A common splint, properly applied, will effect more benefit than an instrument of greater pretension indifferently managed.

From all these considerations, it is apparent that much harm will result, in the great majority of deformities, from the habit sometimes pursued of keeping a deformed part many weeks in succession in an apparatus without the removal so necessary for the purposes of cleanliness, manipulations, and readjustment. Among the evil consequences of too long retention of instruments, often combined with unsuspected excessive pressure, the author has witnessed the production of an opposite kind of deformity, as the conversion of varus into valgus, and a degree of rigidity of the part, which has required weeks of painful manipulations and stretchings, before the natural movements have been possible — sometimes, indeed, restoration of motion of an articulation has been rendered impossible.

The slighter the deformity, the more necessary is frequent removal of the apparatus, because by removal and appropriate manipulations we insure retention of mobility. In severe cases, in which we expect only to effect straightening, and do not anticipate restoration of mobility, frequent removal of the apparatus is unnecessary; for too frequent removal may be hurtful, by allowing the recently elongated tissues to recontract during the time the apparatus is removed from the part.

Division of the hamstring muscles.—We have shown that in a limited number of knee-contractures from disease and accident, section of the hamstring muscles may be required as a preliminary to gradual mechanical extension, or to abrupt violent extension under chloroform. In all cases after tenotomy, extension, whether gradual or abrupt, should be delayed until the healing of the punctures in the integuments. In the knee this healing is seldom complete until four or five days after the operation. The following rules may be given for severing the hamstring tendons: Place the patient in the prone position, and let an assistant make firm extension upon the joint, or desire the patient to endeavor to bend the knee, by either of which means the tendons will be rendered prominent. In general follow the directions laid down for the division of the tendo Achillis (p. 338). In severing the tendon of the biceps femoris, insert the tenotome in the adult an inch above the apparent point of contact of the tendon with the fibula, remembering the proximity of the external popliteal nerve, and keeping, therefore, the tenotome close to the tendon. The semi-tendinosus being very superficial, is readily severed by a puncture, where it springs up most prominently; the semi-membranosus being more bulky and fleshy, as well as more deeply seated, requires a larger sweep of the end of the tenotome. It is scarcely necessary to recommend caution as to the important nervous, arterial, and venous structures of the popliteal region. After section of the inner hamstrings, the pressure of the assistant's hands upon the limb being continued, bands of fascia and nerves make themselves prominently felt in the ham. Troublesome numbness in the calf, and unusual pain during extension, has followed the unnecessary division of these structures. It is desirable to apply promptly a pledget of lint and suitable pressure by a bandage over the punctures, to prevent oozing of blood into the areolar tissue of the ham, which affords an inconvenient nidus for suppuration. By adopting this immediate covering and pressure over the puncture, we have never witnessed delay in healing beyond four or five days, in ordinary moderate temperature. Very cold weather may cause tenotomy-punctures in limbs of weak circulation to appear, at the end of several days, as if they had been effected an hour previously, no attempt at adhesion being made. It is therefore proper in cold weather to envelop the limb in flannel, and to assist the reparative powers of the patient by generous diet.

Forcible subcutaneous separation of the tibia and femur in true bony ankylosis of the knee-joint.—This operation, originally proposed and carried out successfully by Langenbeck, and Gross of Philadelphia, has been performed in this country, with some modifications, by Mr. Little, at the London Hospital. The operation consists in making a small incision in the integuments and fibrous tissues at the side of the articulation parallel to the plane of the natural articulating surface of the tibia. The length of this incision should correspond with the width of a narrow sharp-cutting, well-tempered ordinary chisel, say two or three lines in width, which being driven in different directions between the ends of the femur and tibia, united by osseous material, so effectually weakens the connection between the adherent surfaces, that straightening and bending of the limb can, with the exercise of "gentle violence" with the hands, be readily effected. When the surgeon remembers that the *joint* has been destroyed by the diseased process which produced the bony ankylosis, he will not be surprised to learn that this surgical subcutaneous chiselling asunder of bones is not followed by any of the serious consequences known to follow wounds of the joint, and that with or without simultaneous section of knee-tendons, as may appear requisite, the limb may be placed in the desired curative position. It may seem superfluous to remark that the operation is perfectly safe in the hands of the surgeon who avoids injury of the important nerves and vessels about the articulation. It cannot fail to become a standard operation for relief of knees affected with *bony* ankylosis in a bent position, and is in every respect infinitely preferable to the operation of knee-resection when it has been performed for mere ankylosis.

Division of muscles in the vicinity of the hip-joint.—Though in hip-contractures the majority of the muscles proceeding from the pelvis on the flexed side of the part are contracted, experience teaches that few require operative interference. We have many times severed the origins of the adductor longus, adductor brevis, and pectineus, the tensor vaginæ femoris, and the superior origin of the rectus femoris. But of late years we have commonly restricted the operation to the tendon of the adductor longus, for the relief of tense abnormal approximation of the thighs, in cases of general spastic rigidity of the lower extremities. The adductor longus, from its position, exerts a relatively greater influence in morbidly adducting the thighs than other muscles. Its division is a satisfactory starting point for subsequent benefit from manipulation and use. It is effected according to the general principles of tenotomy, and requires no particular description.

Section of the tensor vaginæ femoris and rectus is suggested in certain cases of paralytic contracture of the hip, in which atony of the adductors of the thigh exists, a state of things opposite to the last-mentioned kind of case. Here the thigh is drawn from its fellow, the trunk tending to fall to the ground, as it were, between the thighs. Where contraction of these muscles exists, the paralysis of the adductors and other muscles of the hip (psoæ and glutei) is usually so considerable, that little radical good results from the operation. It should, therefore, as a rule, be superseded by manipulations, frictions, and mechanical appliances.

Division of the flexor tendons of the fingers and toes.—The phalanges, when contracted from articular complaints, require treatment similar to that of the larger articulations. Commonly it is the flexor tendon which is implicated. Enough has been stated concerning the large ginglymoid articulations to render many details of treatment of these small articulations unnecessary. In operating on the fingers, we have to consider beforehand whether the articular disease has left the joint in a condition to resume its functions as to movement; for if we may not expect to recover mobility, a straightened finger is not preferable to one partly bent. We require also to calculate the chance of the tendon when operated on in the course of the theca becoming agglutinated to the theca, and the finger subsequently on that account not regaining movement. In the foot, the most frequent affections of the toes for which surgeons are consulted are those resulting from improper shoes worn during the growing period of the foot—in childhood and adolescence. The great toe is often thrust inwardly, and overlaps the next toe, the metatarso-phalangeal articulation being inflamed and ultimately deteriorated as to the normal condition of the articular surface, with consequent impairment of mobility and very troublesome lameness. [Hueter[1] advises that the head of the metatarsal bone be excised for the enlarged and painful joints caused by imperfectly-fitting shoes or other causes, giving rise to the deformity which is termed "hallux valgus." The disability may be so great as to prevent walking. This operation he performs by making a straight incision on the inner edge of the foot, cutting off the head of the bone with bone-forceps or saw, and bringing the toe into line. Dr. Hamilton, of New York, has reported eleven cases of this operation, with one death and ten successful cases; the results were satisfactory in the successful cases, and the disability more or less completely removed. The fatal case was that of an old gentleman, 75 years of age, who had suffered from an extensive disease of the joint with suppuration, for three years. Dr. A. N. Blodgett, of Boston, has performed the operation three times with complete success, union taking place by first intention, and with a cure of the deformity and disability.] The joint is inclined to stiffen in the extended position after subsidence of the irritation or inflammation, the individual being prevented standing tip-toe, or ascending a hill, without pain or inconvenience. This condition of things may, before and about puberty, be remedied by rest and suitable topical applications, followed by manipulations; the interposition of a partition between the toes, so as to keep the great toe in a proper line with the margin of the foot; and the temporary use of a suitably wide shoe. In long-standing cases, in which the extensor tendon of the great toe becomes rigidly contracted and structurally shortened, and has become dragged outwardly away from its normal situation above and parallel to the metatarso-phalangeal articulation, the section of this tendon may afford relief.

---

[1] [Klinik der Gelenkkrankheiten.]

Another common troublesome defect in the toes, similarly produced, though sometimes hereditary, is fixed flexion of the second toe. In children under the age of ten or twelve years, this defect can usually be remedied by light gentle bandaging (not tight) of the part, upon a padded whalebone splint, night and day, for a few weeks. In older subjects, and in peculiarly rigid cases, section of the flexor tendon, opposite the first phalanx, followed by bandaging on the splint, is a prompt and certain means of cure.

The little toe is often extended upon the metatarsus, or thrust laterally and inwardly and sufficiently prominent to become continually a source of pain and irritation from the shoe. This also is often a congenital affection. Division of the extensor tendon, and bandaging, afford relief.

The toes, and particularly the great toe, are often contracted in cases of varus, congenital and acquired. These contractions are relieved by the means taken to cure the talipes, and sometimes by gradually improving their position with suitable bandages.

[The danger incurred in brisement forcé is, 1st, of fracture or separation of the epiphysis; dislocation; injury to the nerve; laceration of the skin; rupture of the artery. Of these, the most common is fracture, which occurred in 39 out of 119 of Nussbaum's cases. The danger of this is avoided to a degree by tenotomy, but not entirely. Brodhurst has employed forcible flexion in 260 cases, and has met with no accident of any sort. Bauer has used brisement forcé in 600 cases of contraction and ankylosis, with such success as to warrant his recommending this instead of gradual straightening. In a few cases, however, fracture has occurred. The femur has been purposely broken in deformity from ankylosis of the hip in a faulty position by Stanley,[1] Tillaux,[2] and C. F. Taylor.[3]

The latter employed in one case an ingeniously-devised osteoclast for the purpose, with an excellent result.

Rupture of the popliteal artery occurred in one case of forcible straightening of the knee, under the care of Dr. C. D. Homans; the femoral artery was tied, and the patient ultimately recovered.[4]

At the knee-joint, to diminish the resistance, it is always advisable, if possible, to loosen the patella before straightening the limb; this can sometimes be done by pressure from the outside by a key. Recently, however, the patella has been separated from the femur by a chisel, and also by a subcutaneous saw, and the limb successfully straightened.[5]

Rhea Barton practised the excision of a wedge-shaped piece of the shaft of the femur above the condyles, fracturing the bone remaining uncut. Buck modified this procedure by including in his wedge the condyles and the head of the tibia. Dr. Gross collected 21 cases of this operation, with 4 deaths from pyæmia. Pancoast, Brainard, Gross, and others have drilled through the bone, using a small drill, at the point destined for fracture, and then straightened the limb.[6]

For ankylosis of the hip-joint, with deformity, Rhea Barton performed section of the femur below the trochanter major. Sayre subsequently modified the operation by making the division with a chain-saw above the trochanter minor. Adams makes a section of the neck of the femur with a subcutaneous saw. He has collected 22 cases of his operation, with 2 deaths, one with pyæmia. One of Mr. Adams's cases was able two years after the operation to walk eight miles. The operation has been successfully performed also by Golding Bird, Jessop, Sands, Lund, and Bryant. Mr. Adams has never obtained motion after the operation, but this was gained in the cases of Jessop, Sands, and Lund. The operation is done as follows: the tenotomy-knife is entered a little above the top of the great trochanter, and carried straight down to the neck of the femur, dividing the muscle and the capsular ligament; a small

saw is carried along the track made, and the bone sawn through. A narrow chisel can be used instead of the saw. Gant, Golding Bird, Hamilton, Maunder, Croft, Brodhurst, and Porter have divided the femur below the trochanter, where it was impossible to define the neck to execute Adams's operation.

Volkmann[1] reports having performed subtrochanteric osteotomy 12 times, with entire success. In six cases he has performed resection of the hip, using the chisel to remove, after section, the head united with the pelvis, in order that no union may take place and the patient have motion. Success, with establishment of motion, is reported in all. He uses the strictest antiseptic precautions.[1]

Forcible extension.—Under the head of *manipulations* and stretchings, the value of *gentle* employment of pressure and movements with the hands (passive exercise), both as a means of curing slight deformities, and as an important auxiliary to other methods of treatment, has been shown. If a larger measure of pressure or force be used with the hands, the treatment becomes that denominated *violent extension.* Here, as elsewhere, it is difficult to draw an arbitrary line, and say where gentle manipulation ends, and violent extension begins. In the practice of manipulations, the competent operator may frequently avail himself of the smaller degree of sensitiveness displayed by some patients, or of the momentary abstraction of the patient's volition from the muscles (a circumstance instantly felt by the hand of the operator), and apply an amount of force which approximates to, or may be considered as, violent extension. But *violent* extension with the hands is rarely efficacious in the removal of considerable contraction and deformity, especially in full-grown persons, because either the pain produced is intolerable, or the voluntary resistance offered by the muscles of the patient exceeds that at the command of the operator; a struggle is maintained between the patient's muscles and the surgeon or rubber, in which the latter is commonly not victorious.

Through the inability of one person to effect, with any effort of his will, an extension forcible enough to overcome severe contraction, violent *sudden* extension, by means of the combined strength of several assistants, or by means of powerful screws, brought suddenly into action, was proposed and carried out, with varying success and misfortune, by Louvrier, Dieffenbach, and others. In the less severe cases of deformity, those indeed which are curable by gentler means, without longer duration of treatment, the parts were *suddenly* straightened by violent extension, without ultimately mischievous results, and the expected benefit was obtained. But in severer cases of deformity of many years' existence, in which organic changes of greater magnitude had taken place, as in severe knee-ankylosis from extensive suppuration about the articulation, with necrosis, the violent separation of adhesions, and snapping asunder of bony deposits in the popliteal space and elsewhere, were accompanied with laceration of bloodvessels and nerves, fractures of the bones themselves, and consequent inflammation, suppuration, and even mortification of the member. The plan was deservedly denounced, and fell into disuse.

Forcible extension under chloroform.—Surgery received an invaluable addition to its means of usefulness by the discovery of the anæsthetic properties of ether and chloroform; and orthopædic practitioners, following the example of Langenbeck,[1] promptly availed themselves of the assistance these means are calculated to render in the cure of deformities. Hence the employment of forcible extension with the aid of chloroform or ether. By chloroformization, the two great obstacles to the employment of force adequate to straighten or bend a contracted limb, namely, pain and voluntary muscular resistance, are removed. As soon as these impediments disappear, the hands of the single operator, and his single mind, applied to the parts, encounter the physical resistance only of the deformed parts; comparatively gentle manipulations now acquaint him with the nature and amount of difficulty; he can feel his way in the application of greater force; can feel and perceive the resistance of parts successfully overcome, in an anatomical order; if greater rigidity still oppose, a few movements of the joint backward and forward prepare the way for a more extensive yielding; and often the practitioner has the satisfaction of being able thus to effect every natural movement of the joint.

Chloroformization, with manipulations, and the use of a certain degree of force, may be of service as a means of diagnosis. By it the practitioner is enabled, in some degree, to ascertain what proportion of the deformity is due to shortening of soft parts, how much mischief the articular surfaces have undergone, and what amount of restoration is practicable.

After straightening or bending the limb, as the case may have required, by means of this forcible procedure, the part should be lightly secured in a retentive instrument or upon a common splint, adjusted so as to maintain a position more favorable than that in which the limb was before the operation, though not so as to keep it in the new position, *i. e.*, the entirely straight or bent position into which the hands of the surgeon may have brought it. For as soon as the effect of the chloroform disappears, the patient arouses to the conviction of the violence which may have been employed, the part may be acutely painful, and incapable of sustaining the pressure of a tight bandage or ligature.

We usually content ourselves with the

London Clinical Soc., vol. x.; Lancet, Dec. 22, 1877; Boston Med. and Surg. Journ., April 18, 1878.]

[1] Commentatio de Contractura et Ankylosi Genu, novo methodo violentæ extensionis ope sanandis. Berolini, 1850.

increased knowledge obtained of the nature of the case, with the satisfaction of knowing that the part can be improved in form and function, and as the resisting parts have once yielded, that they will afterwards oppose less resistance to replacement; whether the means subsequently employed should be simple manipulations, the use of mechanical apparatus, or repeated administrations of chloroform, and forcible extension. The surgeon who should attempt the forcible binding down of a long-deformed limb immediately after forcible extension, would betray a lamentable ignorance of the pathological condition of the parts in the immediate vicinity and within the diseased articulation. Although the muscular structures may have yielded under chloroform, and indurated fasciæ and old adhesions may have been overcome by stretching and tearing, it will be remembered that much adaptation on the part of nerves, bloodvessels, and absorbents to the altered position of the structures, needs to be accomplished. We find that, by taking moderate means of retaining as much improvement after the forcible extension as can be borne by the sufferer, by the unsparing use of lotions of spirit or by ice applications, and by the internal use of morphia, dangerous inflammation of joints thus straightened has been averted. By employing afterwards the ordinary means of gradual extension, we have straightened joints which would otherwise have required many months of ordinary treatment.

It is perhaps not superfluous to remark, that the use of forcible extension is less defensible in cases of recent disease of articulations than even other active attempts to restore the form in such cases. In a diseased joint the practitioner has to note not only the local disorder, but also the general condition, of which the local affection is but one manifestation. When the surgeon, with ability and experience, has cured the local disorder, *i. e.*, removed the inflammation, healed the ulcerated or suppurating parts, or effected subsidence of pain, heat, and tumefaction, the consequences of the diseased action, contracture and rigidity only remaining, he has not necessarily cured, by internal and general therapeutic measures, the morbid constitutional state. This often slumbers after subsidence of the local disease; and he should pause ere he too hastily undertakes the restoration of form and movements by forcible extension under chloroform, or by other active measures, and thus incautiously evokes a renewal of local disorder.

These views were enunciated[1] some years ago by the author, perhaps with more leaning to the employment of forcible extension. It will be found that violent extension is necessary in a relatively small number of cases, provided gentler means are suitably carried out. Orthopædy is capable of curing all those contractions in which the innervation is not hopelessly disturbed (severe paralysis and spasm), and those in which the synovial surfaces, cartilages, and articular extremities of the bones are not disorganized from disease. When we cannot hope to do more than straighten the limb, as in long-standing hip- and knee-contractions from articular diseases, violent extension under chloroform is most opportune as a means of obtaining a more useful position of the member.

The expectations of surgeons some years ago of the benefit likely to result from operative interference in cases of partial hip-ankylosis, so as to produce a new or artificial joint, have not been verified. Excision of the head of the femur, owing to inability to deal effectually with co-existent disease of the acetabulum, has been less successful than elsewhere. In long-standing hip-ankylosis, be it false or true, if we should be unable to straighten the member by gradual mechanical treatment, or by forcible manipulation under chloroform, there is one resource available, that of severing the bone by subcutaneously sawing or drilling it, below the trochanter, where it most nearly approaches the surface.

In a few cases at the other extremity of the pathological scale, in which the will alone, or timidity, or the peculiar abnormal state of the system exists which is met with occasionally in young persons of both sexes, in whom in consequence of slight injury, a limb remains stiff in the straight or bent position (emotional or ideal paralysis), the part is relaxed under chloroformization, and the contracture is often by this means promptly and permanently cured. True hysterical contractures yield with equal facility during the anæsthetic state; but they usually return when the effect of the chloroform has passed off. In some of the severest hysterical cases which the author has met with, recovery has taken place after the lapse of a few months, or a year or two, either spontaneously, or from the effect of altered dietetic, social, or climatic influences.

[1] Treatise on Deformities of the Human Frame, 1853.

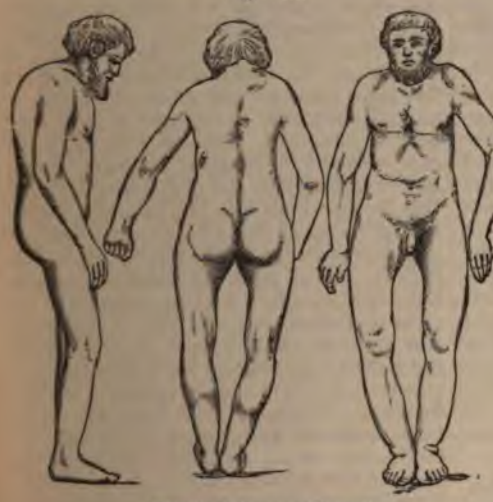
[ADDENDA.

INEQUALITY IN THE LENGTH OF THE LOWER LIMBS.

This has hitherto been regarded as an exceptional deformity. Dr. Hunt[1] called attention to the fact that symmetry is exceptional rather than the reverse. Drs. Cox, Wight, Roberts, and Dwight have made careful measurements of 114 healthy persons and 19 skeletons, and have found that "the greater number of limbs, comparing the limbs of the same person, show a difference in length. About one person in every five has limbs of the same length." The difference is usually from one-eighth of an inch to an inch.[2]

Mr. Callender, after examining 40 persons, found only two with limbs of unequal length;[3] but Dr. Morton (Surgery in the Pennsylvania Hospital) brings additional evidence in favor of the idea that asymmetry is the rule. In 513 boys examined, between the ages of eight and eighteen, the limbs were unequal in length in 272.

Fig. 743.



Osteitis deformans (Bryant).

Osteitis Deformans.

Paget[1] has described an affection which he has termed osteitis deformans, which attacks usually the long bones of the lower extremities and the skull. The bones enlarge and soften; those bearing weight yield. The necks of the femora may become nearly horizontal, but the limbs remain strong enough to support the weight. The disease is attended with pains in the affected bones. Thickening of the bones is found, in the walls of the shaft and in the articular surfaces. The disease begins in middle age or later.[2]

Deformity from Union of Fractures in a Faulty Position.

This subject has receetly been carefully investigated by Dr. Roberts,[3] who advocates refracture at a period after the first injury, much longer than has been previously thought feasible, and reports a successful case of a badly united fracture of the femur operated on six months after the original break.

The most favorable cases are those where the fragments have united at their extremities. If there is lateral apposition, there should be power applied at right angles to the plane formed by the lapped ends. The easiest way is to break with the hands, using a hard surface as a fulcrum. The joints can be protected by bandaging a splint along the limb over each joint. A screw force, as furnished by an osteoclast, can be employed; and it may be necessary to drill the bone to aid in the break. In some cases a powerful extension applied first appears to be of service.[4]

AFFECTIONS OF THE MUSCULAR SYSTEM.

By T. Tatum, Esq. (1862), and
J. Lockhart Clarke, Esq., M.D., F.R.S. (1870).

Revised by P. S. Conner, M.D.

Although muscles are so much exposed to accidents and violence, they are not readily injured; nor, considering their high organization, are they frequently the seat of disease. Muscles may suffer from contusions, strains, rupture, and wounds of different kinds. Severe contusions are frequently followed by temporary loss of power in the muscle; this, together with the extreme pain in any attempt to move the part, particularly in the neighborhood of the large joints, sometimes leads to the suspicion of more serious injuries, as fracture or dislocation. Strains of muscles are often followed, especially in later life, by pains of a lasting and troublesome character, partaking of the nature of rheumatism. Muscle may be ruptured either from external violence or from the too energetic action of its own fibres; this latter occurrence is by no means a common one, especially that in which the entire muscle is torn across. In the living body, muscle offers a greater resistance to a force tending to rend it than either tendon or bone; and when it does give way, it is for the most part at its point of junction with the tendon. Sédillot[1] says, that in twenty-eight cases of rupture of muscles, thirteen were ruptured at this point.

The power of resistance in a sound and healthy muscle in a state of full tonicity is enormous; and many interesting comparisons and calculations on this subject will be found in Borelli, De Motu Animalium. Percy[2] relates the case of a person with wry neck, who was suspended by the head, with a view of putting the muscles on the stretch; the result was separation of the muscle from its insertion, but no laceration of its fibres; and in a case in which the thumb was torn off, the tendons were drawn out, but the muscles were left uninjured, except at the point of junction with the tendon. We are all familiar with the fact, that the tendon of the rectus femoris and the tendo Achillis give way rather than the fibres of their respective muscles. With the loss of its vital contractile power, muscle loses its advantage over tendon, and the experiments of Richerand and others fully establish the fact, that after death, muscle is more easily ruptured than tendon. We observe this when a limb is forcibly straightened from the bent position after the muscles have become unusually rigid from convulsions before death; here laceration of the muscles, and not of the tendons, takes place.

Though muscle in the living body is not often ruptured, yet cases of rupture occur sufficiently often to have given most of us one or more opportunities of witnessing it. Sédillot has recorded no less than twenty-eight cases of entire or partial spontaneous rupture of muscles; but he observes, that no voluntary act can occasion a rupture of their fibres, however powerful the effort may be, and this for two reasons: 1st, because, under the influence of the will, all the fibres of a muscle, and the muscles associated with it in its action, contract uniformly, simultaneously, and in a regular order, to overcome a resistance; and 2dly, because at the moment that the will perceives that the power opposed to it is greater than its efforts can overcome, it ceases to strive further. Rupture, therefore, can only take place when, in some involuntary or instinctive effort, as in the endeavor to recover the equilibrium in a false step, or from some similar cause, the whole force is thrown in a violent and unexpected manner upon one or two muscles, or even on a few fibres. [While this is true of healthy muscles it is not so of those which have undergone the vitreous degeneration in consequence of existing acute grave pyrexia. Such muscles may give way either in part or wholly in the effecting of voluntary movements of some slight extent.] Among the cases collected by Sédillot, is one in which the rectus femoris was ruptured. In another case, the psoas magnus muscle was found ruptured after death, the patient having died from inflammation and suppuration following the accident. The complete rupture of the biceps muscle of each thigh occurred in a man falling from a height; and the two recti abdominis were ruptured at their upper part in a young man, in the struggle to save a tray of cement as he was falling from a platform.

[2] Journal général de Médecine, vol. lxi.

It more frequently happens that a few fibres only of a muscle are ruptured, and this usually occurs in the gastrocnemius.[1] Muscles are sometimes torn across in violent paroxysms of muscular spasm, as in tetanus. In these cases the ends of the muscle, from the violence of the retraction, are thrown into considerable swellings.

In a case of acute traumatic tetanus, under Larrey, the man was immersed in cold baths, after each of which the convulsions and muscular contractions were most severe, and he died in three hours; a swelling, however, had been previously observed below the umbilicus, on the right side. On a post-mortem examination, it was found that the tumor was occasioned by the retracted ends of the rectus, which was entirely torn across. The space between the two ends of the muscles was filled with blood.—Mr. Curling describes a case in which portions of both recti abdominis were ruptured by tetanic convulsions (one of the specimens is in the Museum of the College of Surgeons).—Mr. Gray exhibited, at the Pathological Society, the rectus muscle of a patient who had died of tetanus, in whom almost complete transverse laceration of the muscle had taken place.—In Mr. Earle's case of tetanus, described in Med. Chir. Trans., vol. vi., one of the psoas muscles was partially ruptured.—Boyer relates the case of a strong man admitted into La Charité with "bilious fever;" an emetic was given him, and whilst vomiting, acute pain was felt a little below the middle of the left rectus abdominis muscle. On examining the part, there was neither tumefaction nor discoloration of the skin, but an indentation, into which the fingers could be placed, was felt. The man died; and the muscle was found completely torn across, the two ends being an inch apart, and the space between filled with blood.

The rupture of a muscle is accompanied by extreme pain, resembling that occasioned by a smart blow from a whip or stick, and often by a distinct sound like the snapping of a cord; all motion of the part is either impossible, or is accompanied by such severe pain, with spasmodic twitching, as to cause the patient to desist. [Rupture of degenerated muscles may occur without any symptoms manifesting themselves, the accident being unsuspected during life, and its existence revealed only upon post-mortem examination.] If the muscle be a superficial one, a deep indentation will be found at the seat of rupture, produced by the retraction of its divided ends; and often a considerable swelling, proportioned to the vigor of the contraction of the torn fibres, as in tetanus; and as there is always extravasation of blood, much discoloration of the skin will follow. The indentation and extravasation are not apparent, however, in ruptures of the deep muscles, by which their diagnosis is rendered less clear. If the rupture be discovered early, and judiciously treated, a sufficient approximation of the divided ends will result, good union will follow, and the function of the muscle will be restored. If, on the other hand, it be overlooked or maltreated, or if it occur in a part where proper measures cannot be employed to approximate the ends of the muscle, as in some parts of the trunk, in ruptures of the deep muscles about the hip and shoulder, etc., it will be found that a wide separation exists, and that the ends of the muscles instead of uniting, have become attached to the parts in the immediate neighborhood, and the use of the muscle is consequently lost.

The treatment consists, 1st, in placing and retaining the part in a position most favorable for relaxing the muscles; and 2d, in approximating the separated ends to one another by even compression, which we know exercises so great a power in controlling and modifying the excess of contraction in the muscles, in fractures, etc. As regards the first, this is easily accomplished in the limbs: thus in rupture of the rectus femoris the knee is straightened, and the limb is raised to an angle with the body, as in fractured patella; but where the rupture occurs in the trunk, this cannot be done so readily; yet in the case above mentioned, in which both recti abdominis were ruptured, a good union was effected by keeping the patient in a sitting posture, the body being bowed forward, together with proper bandages.[1] The second is accomplished by an even and uniform compression of the muscles by means of carefully-applied flannel bandages, or laced belts, aided in some cases by a strip of leather or gutta-percha. [Better by the application of the plaster-of-Paris or other immovable dressing, or the elastic bandage of Martin.] At the end of from a fortnight to three weeks, the union is generally completed. The process of union is similar to that of other structures; the effused blood is absorbed, plastic lymph is poured out, which assumes by degrees the firm and resisting character of tendon, muscular fibre itself being never reproduced. When a muscle, with the integument and parts around, is divided, it retracts to a greater extent than where the muscle alone gives way, from being deprived of its collateral support. This, in conjunction with an open wound, renders it extremely difficult to approximate the retracted ends of the muscle, and to find means for retaining them in a proper position; hence it will be found that wounds extending through muscles are followed by nearly complete loss of their use, the great chasm between their ends being filled up by granulation. It is recommended to endeavor to bring the ends together by sutures. [The use of sutures has been advised even in cases of subcutaneous rupture.] These, with a position favorable for the approximation of the ends, and such encircling supports as can be employed where a wound is present, may do much towards restoring the muscle to a certain amount of usefulness.

[1] Richerand, Nosographie chir., vol. ii.

Inflammation of muscle.—Independently of rheumatism, muscles may be the seat of inflammation from various causes, both simple and specific, which may terminate in abscess, or in some morbid changes of structure, to be described hereafter. Inflammation followed by abscess occurs occasionally in the parietal muscles of the abdomen, arising either from some injury or without apparent cause. It appears first as an extremely painful, and more or less circumscribed swelling, distinctly felt below a portion of the muscular planes: after a time obscure fluctuation is perceived; pain is now very great, especially on the least movement, accompanied by irritative fever. On laying open the abscess, pus, discolored and somewhat offensive, escapes, the symptoms quickly subside, and the cavity readily fills up and heals.

Purulent deposits in the pectoral muscles, extending to the intercostal muscles and diaphragm, occurred in a case described by Mr. Hacon in Path. Trans., vol. v., p. 329. The patient had rigors and other symptoms of fever ten days before his death, with great pain in the right hypochondriac region; formation of matter was suspected, and pus followed the introduction of a needle. There were no purulent deposits in any viscus.

Secondary deposit of pus sometimes takes place in muscles as well as in other structures. A case is given of phlebitic suppuration in muscle, originating in what he terms puerperal rheumatism, by M. Cruveilhier.[1]

Inflammation may occur in muscles as a symptom of secondary, or rather tertiary, syphilis. In a paper read before the Royal Medical and Chirurgical Society in January, 1845,[2] Mr. Tatum describes a group of three cases, two of which were associated with other symptoms of constitutional syphilis, whilst the history of the third case was obscure. The disease, which he had not seen described before, appeared in the form of rounded enlargements in the left sterno-cleido-mastoid muscle; there were three swellings in two of the cases, and two only in the other; in one of these there was also an enlargement in the tendinous origin of the muscle; the tumors were evidently formed in the substance of the muscles, and were nearly of the size of a pigeon's egg, and gave a singular beaded appearance to the muscles; there was stiffness, with much tenderness, in the part, and great pain when the muscle was in action; the skin was neither adherent nor discolored; the disease was slow in its progress, and had remained nearly stationary for some months. All the cases occurred in females, probably from the neck being more exposed than in men; in each case the effects of the iodide of potassium were manifest. In the first case the patient obstinately refused to take the iodide of potassium, in consequence of which mercury and various other remedies were tried without any good effect. After some time she consented to take the iodide of potassium; from two to three grains were administered thrice daily, and the iodine ointment was applied externally; the tumors soon began to diminish, and in less than six weeks completely disappeared. The other two cases were similarly treated with complete success; but in one of them the patient was obliged to lay aside the remedy for a time, during which it was remarked that the tumors became stationary; on her resuming the medicine, however, all remains of the disease quickly left her. What constituted the swellings could not of course be ascertained from these cases; but a case occurred some time after, in which there was a tumor in the middle of the biceps muscle, so hard and defined as to induce the surgeon to proceed to its removal by operation, when, on cutting into the fibres of the muscle, no tumor was visible, but the muscle in that part was congested and infiltrated with a grayish kind of lymph, great part of which oozed away with much blood, all the swelling subsided, and the wound healed, leaving no enlargement. Much light has been thrown upon the nature of these affections of the muscles and the changes they undergo by M. F. Bouisson, of Montpelier, under the title of *Tumeurs syphilitiques des Muscles.*[1] According to him, both tendons and muscles are the seats of syphilitic tumors and contractions, which occur in conjunction with other symptoms of constitutional syphilis. He has observed these tumors in the gluteus maximus, the vasti, trapezius, the sterno-cleido-mastoid; also in the muscular structure of the tongue, lips, and pharynx. With regard to the treatment, he for the most part found the iodide of potassium, given internally, with the external use of the iodine ointment, very effectual in removing the tumors, except those of the tongue and pharynx, which were very obstinate; in these cases the muriate of gold, in doses of from $\frac{1}{16}$th to $\frac{1}{8}$th of a grain, was given with success. M. Bouisson was fortunate in having opportunities of seeing this disease in its advanced stages, as well as the stage above described. He found the enlargement continue with little change, except under the treatment of the iodide of potassium, etc., for a considerable period. Sections of the tumors presented an infiltration and deposit between the fibres of a gray plastic exudation; many of the muscular fibres were nearly colorless. This state may be followed either by a softening of the effused matter and its conversion into a kind of mucilaginous fluid, or may form an abscess, which, on slowly getting to a head, may burst, and leave an unhealthy ulcer with sloughy surface and foul discharge. Some of these enlargements, instead of suppurating, harden and become converted into cartilaginous or even bony structure.

[2] Lancet, Feb. 1, 1845, p. 136.

[1] Gazette médicale de Paris, July, 1856.

A case is described in the Gazette des Hôpitaux, January 16, 1858, of a tumor involving nearly the whole length of the sterno-cleido-mastoid muscle. When the muscle was contracted, the swelling was immovable, but in the relaxed state it could be moved on the deep plane of fibres; the skin, though not adherent, did not slide readily over it as natural, and there was a slight blush on it; there were dull pains in the part, which occurred at uncertain intervals, not more by night than by day; neither respiration nor deglutition was impeded. There were decided traces of old constitutional syphilis, as in most of the cases reported. The patient was about to undergo a course of the iodide of potassium.

Sometimes these swellings assume the form still more completely of defined tumors.

M. Robert[1] describes a case of a tumor which formed in the calf of the right leg, as large as an egg, hard, unequal, and lobulated on the surface, somewhat movable, tender to the touch, but not painful, which was completely cured by the iodide of potassium.—In Path. Trans., vol. vii., a very interesting account of a tumor is given by Mr. S. Jones; the tumor was removed by Mr. South from a patient in St. Thomas's Hospital, November 6, 1855. The patient had had syphilis eight years before, when he took mercury, but had no constitutional symptoms. He had received a blow on the left shoulder two years previously, and lost for some time the use of the arm; he, however, gradually recovered it after some months. He had pains in the shoulder, which were considered rheumatic, and were treated and cured by the iodide of potassium; nodes also presented themselves at several points, but they disappeared. Violent pains again came on in the shoulder, which were followed by a tumor in the infraspinal region of the scapula; this increased rapidly in size; his general health suffered considerably. The tumor was well defined, moved only with the scapula, did not project much above the surface, and measured 6$\frac{1}{2}$ inches in one direction, and 8 in another; it was removed with a large portion of the scapula. On examining it, it was found to be formed in the muscles, but principally in the infraspinatus, though nodules were found in many of the neighboring muscles. The tumor was mostly hard and dense, slightly elastic, of a dead-white color, and of a homogeneous or slightly reticulated structure; the surrounding muscular fibres were directly continuous with its surface, and muscular fibres were present in great abundance in many parts of the tumor. Many of the fibres, examined by the microscope, had lost their striated character, and had become glistening, transparent, and structureless. The spaces between the fibres were occupied almost solely by cells. Mr. South has since informed me that the wound healed well, and there has been no sign of returning disease.

Simple contraction, or shortening of a muscle without apparent alteration in its structure or change from its normal condition, seems to be an occasional effect of the inflammation from syphilitic poison in the system, and is usually found in the muscles of the arm or forearm. M. Ricord has noticed this so long ago as 1842.[1]

M. Notta, in an interesting paper on Syphilitic Muscular Contractions,[2] gives three cases, the features of which were much the same; and in each the biceps was the seat of the contraction. There was no hardness or rigidity of the muscle when not in action; the pains were variable, being great on putting the muscle on the stretch, and mostly referred to its insertion. The contraction was slow, and gradually reached a certain point, causing fixed flexion of the elbow. The iodide of potassium, with minute doses of the proto-iodide, appears to have cured every case. The same may be said of the cases cited by Ricord[3] and others, in which there was a certain change of structure of the muscle, associated with contraction. As a general rule, mercury has done no good; in fact in

[3] Gaz. des Hôpitaux, 1846, p. 1.

many of the cases the disease appeared to increase while the patient was undergoing a course of mercury.

[The syphilitic affections of muscles present themselves under three forms, functional, inflammatory, and myomatous. In the first, which is characteristic of the earlier periods of the disease, there is complaint of pains located in the fleshy part of the muscle or muscles; weakness, sometimes of extreme degree; fibrillary tremblings; and unsteadiness of action. In addition to these symptoms which, more or less well marked, are met with in almost all, if not all cases, there is occasionally observed an insidiously commencing and ordinarily slowly advancing contraction of certain of the muscles of the extremities, almost always the biceps flexor of the forearm. This contracture, which perhaps is due to a sub-acute inflammation (Mauriac), differs in all respects except in the produced deformity from the permanent flexure which at times follows specific myositis. There is no observable change other than "shortening of the muscle with tension and rigidity of its tendon," no pain except when an attempt at straightening the forearm is made, nothing but a progressive flexion carried at times up to or beyond a right angle, which flexion cannot be overcome by force. Commencing sometimes within three months, and usually within the first year, it will if left to itself last for an indefinite period, but under appropriate treatment may commonly be made to disappear within a few weeks or at most months.

The inflammatory affections may as a rule be easily differentiated from ordinary myositis, not only by the existing syphilitic history and lesions, but by the less intense character of their symptoms, and in the more severe cases by the peculiar "woody" induration of the affected muscles. The specific exudation, which is poured out both into the interstitial connective tissue and within the sarcolemma, is ordinarily absorbed, and complete resolution takes place; but at times it hardens, and as the result of such sclerosis the muscular elements are destroyed and permanent irremediable contractures result. This fibrous tissue may undergo calcareous or osseous change. The duration of specific myositis may usually be much shortened, and the likelihood of the development of destructive lesions greatly diminished, by proper medication.

Specific myomata, gummy tumors, while often met with, are rare as compared with syphilitic diseases in general. They may or may not be preceded by inflammation, are frequently symmetrical, and are very variable in size. Usually they may be diagnosticated without difficulty, but at times it is almost, or quite impossible to absolutely determine the specific character of a muscle-tumor. By their presence, they as a rule, give rise to some functional disturbance, and when large, may cause pain, swelling, interference with blood-supply, or even inflammation of adjacent parts. Unlike the diffused exudations of myositis, these gummy tumors are likely not to undergo resolution, but to soften and break down and later destroy the overlying tissues, the resulting ulcers being quite intractable. Suppuration of the tumor itself does not take place. Properly treated gummata commonly disappear, but in consequence of the destruction of the involved muscular fibres, functional impairment in many cases remains.]

Muscular atrophy.—Muscular tissue is frequently subject to atrophy, which may consist of one or more of the following alterations:—

1. Simple atrophy.
2. Atrophy with granular degeneration.
3. Atrophy with fatty degeneration.
4. Atrophy with (the so-called) waxy degeneration.

In *simple* atrophy the degree of wasting of the muscular tissue varies considerably. Generally, the fibres, although paler and reduced in diameter, retain their anatomical characters. The transverse and longitudinal striæ are well marked, the sarcolemma preserves its usual delicate and transparent appearance, and the nuclei it contains are not increased in number. Such is the form of atrophy met with in chronic and exhausting diseases; in cerebral paralysis; after contusions, compressions, and affections of the joints. In many diseases, however, both acute and chronic, simple atrophy, or wasting of the muscular fibres, is accompanied, in a greater or less degree, by one or more of the degenerations above mentioned. Such is sometimes the case after acute fevers, particularly typhus or typhoid; after alcoholism, lead poisoning, rheumatism, etc. But there is another form of this malady, which is known by the name of *progressive muscular atrophy* (Cruveilhier), *atrophie musculaire graisseuse progressive* (Duchenne), and *wasting palsy*. This curious disease differs in several respects from the atrophies above mentioned. It is always chronic, but of uncertain duration; is frequently hereditary; is capricious or irregular in its invasion; prone to spread from one part to another, or become general, and thus go on to a fatal termination. The affected muscles suffer different degrees of wasting, and assume a variety of aspects. Even in the same muscle, bundles in different stages of atrophy and degeneration may be found at the side of others that have retained their normal state. When the wasting is extreme in all the bundles, a long muscle may be reduced to a mere fibrous and cylindrical cord, or to a kind of tendon, and a flat muscle may be reduced in the same manner to a kind of membrane. In some instances the atrophy may be *simple*, that is, the muscular tissue may be wasted to a considerable degree without any granular or fatty degeneration;[1] but generally, one or both of these alterations of structure is found to exist to a greater or less extent. The muscle also changes and varies in color according to the nature and degree of the atrophy. It is paler than natural; occasionally it is quite colorless, like the flesh of fish; or it may have a faint yellow or ochreous tint. Its consistence for the most part is increased in consequence of the increase of the interfibrillar connective tissue. When examined under the microscope, the affected muscles may be seen to have lost to a variable extent and degree, or even entirely, the appearance of transverse and longitudinal striation, while in a corresponding proportion the sarcous or muscular element is transformed into granules, which, in some instances, are too fine to be distinguished as separate particles. The granules are soluble in acetic acid.

Granular degeneration or disintegration of the muscular tissue may exist alone; but frequently it is accompanied by fatty degeneration, or may only form the first stage of the latter change.

Fatty degeneration.—This morbid process may make its appearance in the muscular tissue at once; or may follow, accompany, and altogether replace the granular change. Besides this transformation into fatty *particles*, fat-cells in unusual, and sometimes in great numbers, are found between the fibres, either collected into groups, or disposed in linear succession, like rows of pearls. These cells may multiply in proportion as the muscular tissue disappears, so that, when the fibres are reduced to mere filaments, there may be no loss of volume in the limb. An interesting case of this description is related by Mr. Hallett.[2] The degenerations seemed constantly to have commenced on the surface of the muscles, and extended inwards to their centres; so that many which appeared wholly converted into fat, exhibited, in their interior, muscular fibres in a more or less healthy condition.

Waxy or vitreous degeneration.—This structural change was first described by Zenker.[1] It is called by the French pathologists, *vitreous* degeneration.[2] According to Zenker, it is observable only in the voluntary muscles, and never attacks all the bundles of the same muscle. The essential change of structure consists of a transformation of the muscular tissue into a homogeneous, colorless, and glistening substance, in which the transverse and longitudinal striæ, together with the nuclei, have entirely disappeared. This kind of degeneration is more common after acute diseases, particularly after typhus and typhoid fevers, but occurs also in *progressive muscular atrophy*. Indeed, in this peculiar malady, all the three kinds of degeneration—the *granular*, the *fatty*, and the *vitreous*—may be seen, not only in the same patient, but in the same muscle.[3]

In a large majority of instances, *progressive muscular atrophy* first makes its appearance in one of the upper extremities, especially in the right limb. It begins commonly in the muscles of the hand, first in the thenar eminence, then in the hypothenar, and next in the interossei. [By many the first external interosseous muscle is declared to be the one primarily affected.] When the interosseous muscles are considerably wasted, the hand assumes the appearance of a bird's claw—the *main en griffe*, as it has been termed by Duchenne. If the atrophy extends upwards, the flexors and extensors of the fingers, and sometimes the muscles at the back of the forearm, become involved. When the disease extends beyond these limits, it attacks the muscles of the arms and trunk; the biceps first, then the deltoid and the triceps, the pectorals, the latissimi dorsi, the rhomboidei, the extensors and flexors of the head, the sacrolumbales, the abdominal muscles, the muscles of respiration and deglutition. Occasionally the depressor muscles of the jaw become involved. In some instances the atrophy is limited to the muscles of the forearm, and in others it begins in the muscles about the thorax, and makes considerable progress, while the arms remain unaffected. Sometimes it extends to the lower extremities, but rarely begins there.

The unequal and irregular wasting of the muscles produces in the trunk and limbs a variety of alterations in their shape and position, which are characteristic of the disease; for in ordinary atrophy succeeding exhausting diseases, the emaciation is uniform, as it affects nearly all the muscles of the part to the same extent.

[2] Cornil et Ranvier, Histologie pathologique.

[3] Charcot et Jouffroy, Archives de Physiologie normale et pathologique, 1869, No. 3, p. 363.

The earliest symptom of progressive muscular atrophy is a loss of muscular power in the afflicted parts, especially after exercise or exposure to cold. With this weakness there is an awkwardness in the patient's movements, and a certain loss of muscular co-ordination, arising from the unequal or irregular wasting of the muscles, and the consequent change in their relative force or antagonism when employed in the performance of voluntary movements. Among the other early symptoms are cramps, twitches, and fibrillary tremors in the muscles. Generally the sensibility remains unimpaired, but occasionally there is numbness of the skin, or a certain degree of cutaneous anæsthesia; while, on the other hand, in about half the cases, more or less pain is experienced in the wasting muscles, or previous to their atrophy.

Pathology.—Cruveilhier, who was the first to investigate the morbid anatomy of progressive muscular atrophy, believed that atrophy of the motor nerves was the starting-point of the disease. This opinion was founded on eleven cases in which the motor nerve-roots were more or less wasted. But in the majority of instances in which post-mortem examinations were made, no appreciable alteration of the nerve-roots was discovered. It was therefore inferred that atrophy of the nerves cannot be the actual cause of that state of the muscles; and since no disease of the nervous centres had hitherto been detected, it was further inferred and generally believed that progressive muscular atrophy is a disease originating in the muscles themselves, in consequence of impaired nutrition, resulting from a peculiar diathesis or an hereditary tendency. The more recent supporters of this view were Trousseau, Duchenne, Meryon, Roberts, Oppenheimer, Friedberg, Hasse, Friedreich, Cohn, and others. But in 1861, I discovered in the spinal cord removed from a well-marked case of progressive muscular atrophy, numerous lesions of the gray substance, consisting chiefly of areas of what I call granular and fluid disintegration.[1] In several other cases which I subsequently examined, the same kind of lesions were observed in company with similar alterations of some of the white columns, with dilatation of bloodvessels, or atrophy of the nerve-cells and of the anterior roots of the nerves.[1] Since my first publication on this subject, several German and French pathologists, by means of improved methods of observation, have obtained similar results.[2]

Etiology.—Among the predisposing causes of progressive muscular atrophy, consanguinity, or hereditary influence, is universally acknowledged to hold the first rank. Dr. Roberts collected the history of ten families in which muscular atrophy prevailed, and of these, twenty-nine individuals were attacked. Aran relates that a sea-captain had lost two maternal uncles and a sister by this disease, and that another patient's two aunts had died from the same malady. Meryon's first cases were four boys who had six healthy sisters.[3] In another family two boys were affected, while the two sisters escaped. The male sex is therefore much more prone to muscular atrophy than the female—in the proportion of about six to one. In nearly all the hereditary cases on record, the disease became generalized, and therefore tended to a fatal termination.

Among the chief exciting causes are excessive muscular exertion, cold and damp—especially when combined—and injuries or diseases of the spine. In those cases which are attributable to the influence of cold and wet, the atrophy is generally preceded and accompanied by neuralgia or so-called rheumatic pains in the affected muscles, or in the course of the nerves leading to them. Syphilis, again, appears to be one of the assignable causes of the disease. To this form M. Rodet has given the name of *atrophie musculaire progressive syphilitique.*[4] In some instances no particular cause can be clearly assigned, and these are the cases in which hereditary influence appears to come into operation.

Treatment.—This must of course depend, to a certain extent, on the causes to which the disorder may be reasonably traced. Removal from the influence of cold and damp, or avoidance of undue muscular exertion, is of primary importance. Warm and sulphur baths, especially those of Aix-la-Chapelle, have been particularly recommended. When there appears good ground for believing that the atrophy is attributable to syphilitic taint, iodide of potassium, or perhaps mercury, must be employed. In cases attributable to other causes, vegetable and mineral tonics, cod-liver oil, and phosphorus may be administered. Dr. Meryon speaks very highly of the long-continued use of arsenic. But of all remedies hitherto employed, galvanism is undoubtedly the most useful, when applied to the affected muscles. The benefit derived from it, however, is very often temporary. Remak strongly recommends the application of the constant galvanic current to the spinal column, particularly in the cervical region. The fact, as already stated, that in the advanced stages of progressive muscular atrophy, various lesions have been found in the spinal cord, would suggest the propriety of trying the effects of counter-irritants, particularly setons and blisters to the spine, in the early stages of the disease.

[3] These interesting cases, with the microscopic appearances of the muscles, are recorded in vol. xxxvi. of the Med.-Chir. Trans.

[4] L'Union médicale, No. 26, p. 403, 1859.

There are two other special forms of muscular atrophy, which are peculiar to the period of childhood, viz., the atrophy which follows infantile paralysis, and the degeneration of muscles with apparent hypertrophy.

1. The muscular atrophy of infantile paralysis is extremely interesting to the surgeon, in consequence of the deformities which it so frequently occasions. The period of childhood at which this disease makes its appearance varies from a few months to a few years after birth, more especially during the first dentition. The attack is generally sudden, and frequently preceded by a feverish state which may last a few hours or a few days, accompanied occasionally by convulsions, which are immediately followed by paralysis without loss of sensibility. The paralysis generally begins in the lower extremities, but rarely attacks the upper extremities alone. At first it is more or less general, but after a variable period it restricts itself to particular muscles, or groups of muscles, or to a particular member, and thus becomes localized. The muscles upon which it most frequently fixes are those at the anterior part of the leg—the extensors of the toes, and flexors of the foot; the extensors and supinators of the hand; the extensors of the leg, and muscles of the foot. Sometimes single muscles are affected, and most commonly, the extensor longus digitorum of the foot, the tibialis anticus, the deltoid, or the sterno-mastoid. After a time, varying generally from one to two months, but sometimes much longer, the paralyzed muscles begin to waste, and may ultimately be reduced to mere fibrous bands. Nor is the atrophy confined to the muscles; it involves the bones, ligaments, and other parts.[1]

The paralysis and the atrophies by which it is succeeded combine to produce a variety of deformities and unnatural attitudes which call for the surgeon's skill, either in the application of mechanical apparatus, or in the performance of necessary operations. These deformities consist chiefly of *talipes equinus*, *equino-varus*, *equino-valgus*, *calcaneus*, or *calcaneo-valgus*, and *talipes varus*.[2]

The paralysis itself and the muscular atrophy to which it gives rise are not often fatal. The difficulty consists in restoring the muscles to their normal condition: but this, in many instances, may be accomplished. The remedies recommended by the most experienced practitioners consist of nux vomica, strychnine, cod-liver oil, the preparations of bark and iron; sulphur and salt-water baths; blisters and counter-irritants along the spine; stimulating embrocations to the affected muscles, and especially the application of electricity.

2. *Degeneration of muscles with apparent hypertrophy.*—This peculiar disease was first understood and diagnosed by Dr. Duchenne (of Boulogne) in 1858. Since then it has been recognized and investigated chiefly in Germany by Griesinger, Eulenburg, Cohnheim, Berind, Wernich, Oppolzer, Heller, and Seidel. It begins in childhood, like the malady just described, but often continues up to an advanced period of youth, when the patient is cut off by some intercurrent disease. Its course may be divided into three stages: a stage of partial and incomplete paralysis; a stage of apparent muscular hypertrophy, and a stage in which the paralysis becomes general, and the muscles waste.

The first stage begins with weakness of the lower extremities either before or after the period at which the child should be able to walk. In the former case, when the little patient attains the age of ten or twelve months, and attempts to walk or stand, it falls immediately, and continues unable to walk, even when assisted, for two or three years.

The second stage begins some months—or even as long as two years—after the muscular weakness, and is manifested by a progressive enlargement of the gastrocnemii, then of the glutei and lumbar muscles. This enlargement occurs sometimes in nearly all the muscles, but in general it is limited to a few. The enlarged muscles are firm and elastic, and become very strong during contraction. This condition may remain stationary for some years.

---

[1] Laborde relates a case in which considerable atrophy of the deltoid muscle occurred in four days after the first appearance of the paralysis. De la Paralysie (dite essentielle) de l'enfance, p. 45.

[2] For the description and treatment of these deformities, see the previous article, ORTHOPÆDIC SURGERY.

In the third stage the paralysis gradually increases and becomes more general. The patient is no longer able to stand upright; the upper extremities become affected; the enlarged muscles rapidly decrease in volume; and the limbs and trunk become atrophied *en masse*. In this state the patient may exist for a considerable time, but ultimately dies by intercurrent disease. Many of the children afflicted with this singular disorder have dull intellects, and are occasionally more or less idiotic.

Morbid anatomy.—The morbid anatomy of this disease has been investigated chiefly by Duchenne, in France, and by Eulenburg, Cohnheim, Griesinger, and others in Germany. Nothing abnormal could be discovered in either the nervous or vascular systems. Eulenburg and Cohnheim found the electro-muscular contractility everywhere perfect. To the touch the muscles gave the sensation of a doughy and inelastic mass. They were marked with stripes of a yellow or yellowish-white appearance. At certain points they could not be distinguished by the naked eye from the subcutaneous adipose tissue. There was also great hypertrophy of connective tissue between the muscular fibres, which were frequently much reduced in diameter, although they were not otherwise much altered. Duchenne and Ordoñez found the striæ on the fibres very much finer than usual, and semi-transparent. The same appearance, together with an increase of connective tissue, and large collections of fat-cells, were also observed in one case by myself.[1]

Treatment.—During its first stage the disease is sometimes curable. Duchenne has recorded two such cases.[1] But in the second stage scarcely any hopes of recovery can be entertained. The treatment consists chiefly of local faradization and shampooing.

Ossification of muscle.—The conversion of muscle into fat is truly a degeneration, as it is a change from a highly organized structure into an amorphous mass of adipocere. The same may be said of the so-called bony deposits in many soft parts, which are not true bone either in their structure or their chemical composition; while the ossific growth in muscle possesses all the qualities of true bone, and is merely the development of one organic structure within another, to which the term "degeneration" would ill apply. Mr. Hawkins, in a clinical lecture to which I shall have again to refer, remarks that the ossific deposit in muscle is that of true bone with cancelli, compact shell, periosteum, and cartilage, displaying also under the microscope all the signs of true bone. Mr. Quekett showed Mr. Tatum some beautiful microscopical preparations, which prove the true bony nature of these deposits. Ossific growths may take place over a large extent of the voluntary muscles, or may be limited to one or two points. In the Museum of the College of Surgeons is the skeleton of a man in whom nearly all the muscles of the back had become ossified, large sheets and masses of bone occupying the places of the latissimus dorsi, spinalis, and rhomboid muscles, forming large bony sheets on the back and sides, while large stalactic growths of bone spring from the pelvis, ribs, and scapulæ. The following case is valuable from the circumstance of its progress having been watched from its commencement up to its very advanced state in 1862, when the account was published.

G. Brown, aged twenty-two. was originally admitted into St. George's Hospital under the care of Mr. Cæsar Hawkins in August, 1843,[2] with swellings in the dorsal and lumbar regions, some of them apparently bony. Their appearance was accompanied with severe rheumatic pains. All these disappeared under treatment. They reappeared, however, and then one was removed from between the trapezius and rhomboid muscles; it was intimately connected to both, fibres from both being inserted into it; one end of it was fixed to the spines of the sixth and seventh dorsal vertebræ, the other was smooth, playing on the end of the scapula. After this, for four years, fresh tumors were observed to form in different muscles of the trunk and neck, being at first soft, growing rapidly, then becoming hard, and, after a time, either disappearing altogether under treatment, or leaving a bony deposit behind. This new bone extended slowly towards either extremity of the muscle in ridges corresponding to its fibres. He was now lost sight of, but in June, 1859, again presented himself at St. George's Hospital, with extensive ossification of the muscles, together with several exostoses both on the spine and ribs. The greater part of the latissimus dorsi on either side, especially at the free edges, was ossified; large masses of bone filled up the hollows on either side of the vertebral spines from the sacrum to the occiput, soldering all the bones together into an inflexible column. The ribs were likewise immovable, partly from being ankylosed to the spine, and partly by the ossification of the muscles connecting them with the scapula and spine; so that respiration was entirely performed by the diaphragm. The trapezius, and, apparently, the deep muscles at the sides of the neck, contained large deposits of bone; both scapulæ were immovably fixed to the ribs, principally by the ossification of the serratus magnus and rhomboid muscles. In front, both the great pectoral muscles, from their origins to their insertions, were almost entirely ossified, presenting ridges taking the course of the fibres, and forming large masses at the folds of the axilla. The sterno-hyoid and sterno-thyroid muscles were much ossified; and these, together with the recent appearance of a considerable swelling below the chin, had been accompanied with so much difficulty in deglutition as to alarm him; he therefore came to the hospital to see Mr. Cæsar Hawkins, under whose care he had before been. The fulness in the upper part of the throat was not hard, but very tender; it yielded to a second application of a blister in a few weeks, so that the genio- and mylo-hyoid muscles could be distinctly felt almost entirely ossified. Preparations from this case are in the Museum of St. George's Hospital.

---

[1] Dr. Duchenne has invented an ingenious instrument which he calls the "emporte-pièce histologique," for removing small portions of muscle from the living subject. It is made by Charrière, of Paris, and consists of a steel cylindrical rod, divisible longitudinally into two parts; one of these is fixed to a handle by means of a screw, and terminates at the screw end in a small hollow cone, the base or lower border of which has a sharply-cutting edge. When closed, the two pieces together form a small cylindrical rod with a fine point. As soon as it is made in this state to penetrate the muscle, the hollow cone is opened by sliding down the other half of the rod, and incloses a small portion of the muscle, which it cuts and brings away as the instrument is withdrawn.

[1] De la Paralysie musculaire pseudo-hypertrophique, Paris, 1868; and Archives gén. de Méd., Janvier et seq., 1868.

[2] Med. Gaz., vol. xxxiv., 1844, p. 273.

The cause of osseous growth in muscles is not easily explained. A tendency to increased bony deposit is not very uncommon, and shows itself in exostosis and extension of bony growth into the tendons inserted into the bones; but in ossific growth in muscle it is a distinct formation, and in no way, at first, connected with exostosis. It is of inflammatory origin, as the pain and swelling, and also the effects of remedies, would indicate. Mr. Abernethy mentions the case[1] of a lad in whom either an exostosis or bony growth in a muscle invariably followed a blow on the part. Mr. Hawkins alludes to an account of eighteen cases of bony growths in muscles among the recruits in the Prussian service; these were said to have been the result of inflammation in the deltoid and pectoral muscles. Inflammation of muscle is rare, and excess of bony deposit in the system is not very common; but when they both occur in the same individual, the exudative lymph in the former would seem to be a favorable nidus for ossific deposit. As regards the treatment, no local measures answered in the above case so well as blisters, under which, with the exhibition of colchicum internally, considerable diminution of the swellings and relief of the pain took place. The swellings completely disappeared after a course of the iodide of potassium, at first five, and then seven grains thrice a day in sarsaparilla; but they returned again shortly after, while the patient was still taking the medicine. On the reappearance of the disease, mercury was given, two grains of calomel and a quarter of a grain of opium twice daily, which at the end of three weeks produced sore mouth; again, all the swellings were nearly removed, at first rapidly, then slowly; but a large mass of bone between the scapula and spine was removed, as stated, by operation. After this, from hemorrhage and other causes, his health failed, and he was much reduced, and specifics were laid aside for some time. Numerous fresh tumors having, however, formed, he, in a few months, began the phosphoric acid, first in half-drachm, and afterwards in drachm doses, three times daily, which he continued from April 6 to May 21. The swelling greatly diminished under this treatment, and with the repeated application of blisters their recurrence seems to have been arrested. Thus the remedies appear to have been chosen with a view to the inflammatory nature of the complaint, and to have been most efficacious; yet so strong was the tendency to relapse, that the swellings formed again and again, even under the treatment that had caused them to disappear. They were, however, finally arrested, the blisters having been most conducive to that end.

[Two very different forms of true muscle-ossification occur, the one limited, not at all infrequently met with; the other general, and of great rarity. In the former, of which examples are found in the so-called "exercise-bones," moderate inflammation of the connective tissue, consequent upon slight but frequent repeated irritations, is followed by an osseous transformation, with associated destruction of the sarcous elements from pressure and diminished blood-supply, and much more rarely the deposition in them of lime-salts. In the general form, progressive myositis ossificans, of which the cited case of Mr. Hawkins was an example, a very different state of things exists. Commencing in childhood, or even in infancy, as a hyperplastic inflammation of the connective tissue, atrophy soon follows, and bony transformation succeeds. The muscles of the back or neck are primarily affected, but in time all the muscles of the body, except those which are essential to respiration, nutrition, and reproduction will be involved in the bony change, unless the subject of the disease should die of some intercurrent affection, or from exhaustion, local gangrene, etc. The exciting cause of this necessarily fatal form of myositis is as yet undetermined, but the phenomena which it presents in its course are certainly very like those of amyotrophies of nerve-origin.]

[1] Surg. Lectures, vol. iii., p. 169.

TUMORS IN MUSCLES.

Tumors of different kinds are occasionally found in muscle. Perhaps that which occurs most frequently is the fibrous tumor, of a cartilaginous hardness, and often growing to a considerable size.

A lad, aged fourteen, was under Mr. Tatum's care in St. George's Hospital in the summer of 1860, with a tumor as large as the double fist, at the back part of the left thigh, about its middle; it was extremely hard, and appeared to be a chondroid tumor growing from the bone, so closely did it seem to be attached to it; on relaxing the muscles, however, by bending the knee, it admitted of a certain movement on the femur. The tumor was removed, but not without difficulty, partly from its vicinity to the bone, which it seemed to grasp, and partly that the great sciatic nerve was imbedded in it, and was only freed by careful dissection. The tumor was found to have its origin in the semi-membranous muscle, the lower part of which was healthy, but the part above the tumor was converted into a pale structure similar to the tumor, but less dense, and retaining the form of the muscle, with a slight remnant of fibrous appearance. The tumor was extremely dense, of a semi-transparent, cartilaginous aspect. Some of the fibres of the muscles were spread over the tumor; others dipped into it, but were soon lost in its substance.

Shortly after this, a tumor of a similar character was removed from the deltoid muscle of a young man by Mr. Johnson; it was about the size of an egg, and surrounded on all sides by muscular fibres. Many of the fibres entered and could be traced a considerable way into the dense fibro-cartilaginous mass.[1]

The recurring fibroid, although it does not originate in muscular structure, has a great tendency to be reproduced in it. [Sarcomata, though generally originating outside, are at times primary affections of muscles.]

In two patients under the care of Mr. Hawkins in St. George's Hospital, each of whom had a tumour of this description in the breast, and in whom the tumors returned, and were removed several times, it was observed that when the recurrence took place the pectoralis major was the part principally involved. A man came under Mr. Tatum's care, from whom a tumor of the above nature had been removed from the parotid region, and subsequently a recurring small one from over the masseter muscle; four months after which he became Mr. Tatum's patient, having a tumor about the size of a French walnut in the neighborhood of the second cicatrix. On removing it, Mr. Tatum found that it had formed in the upper part of the masseter muscle, a few fibres of which only remained. A few months after this, he again came under Mr. Tatum's care, with two tumors the size of filberts a little above the site of the last, and which proved, on dissecting them out, to have had their seat in the temporal muscle. Mr. Tatum had a lady under his care from whose breast he twice removed a tumor of the above nature; the disease returned in the pectoral muscle, in which it made rapid progress. The event of this case is not recorded.

Cysts of various kinds are occasionally found in muscles. Some of these cysts contain hydatids. Such is the *trichina* spiralis, a bisexual and minute nematode worm which is reproduced viviparously by the female parent. The female trichina is about one-third longer than the male, and in the mature state contains in its uterus a variable number of ova, as well as free embryos in different stages of development. When the flesh of an animal containing spiral trichinæ is eaten by another, the contents of the small intestines are found, after about twenty-four hours, to contain a multitude of these worms, which lie imbedded in the mucus or in the chyme. Soon after the embryos are born, they begin to migrate from the intestines in search of muscular tissue, upon which they feed and develop. Concerning the manner in which migration is effected, there is some difference of opinion. Most observers believe that the young trichinæ pierce the walls of the intestines and other parts until they reach the muscles; while other observers, with Dr. Thudichum, contend that, after penetrating the mucous membrane of the intestines, they enter the bloodvessels and lymphatics, pierce the lymphatic glands, reach the heart with the venous blood, traverse the lungs, and are then distributed, by the arterial circulation, to all parts of the body. However, having reached the muscles, there they feed, and grow, and ultimately become encapsuled. Leuckart maintains that the young trichina always penetrates the sarcolemma, while other observers asserts that it lives and grows either inside or outside that sheath. However this may be, so long as the worm remains outside, the muscular fibre is not permanently damaged, although it becomes somewhat granular, and loses the distinctness of its transverse striation. But if the parasite pierces the sarcolemma, the fibre is permanently destroyed; the sarcous elements are disarranged, broken up, and transformed into granular masses, which constitute the food of the invader. As the trichina reaches its full growth and becomes fixed to one spot, the interstitial connective tissue and the sarcolemma around it, being irritated and inflamed, throw out an exudation, while the nuclei of both enlarge, divide, and rapidly multiply. The exudation, which appears to consist of fluid fibrin, soon after solidifies and forms a capsule in which the worm coils itself up. At the end of some weeks after infection, fine dark granules of carbonate of lime and magnesia are deposited in variable numbers within the capsule, and render it more or less opaque.

---

[1] Mr. Curling gives an account of a fibrous tumor which he removed from the gastrocnemius muscle of a girl aged nine; its circumference was not very clearly defined from the muscle, so that its more prominent central part only was removed. See Path. Trans., vol. vi., p. 346. Mr. Birkett removed a tumor from the short head of the biceps flexor cruris, of a chondro-osteoid growth, 4½ by 3 inches in size, of a grayish-pearl tint, and of cartilaginous structure; the centre was of bone. Ibid., vol. ix., p. 397.

In man, trichinosis is produced by the ingestion of imperfectly-cooked flesh of animals infested with trichinæ—particularly pigs.

The pathognomonic symptoms of trichinosis are the following:—

Sudden swelling of the face, particularly the eyelids, after the patient has for some days felt prostrate and lost his appetite; fever, with quick pulse and copious perspirations, which have sometimes an offensive odor; painfulness and immobility of arms and legs; the muscles are swollen and contracted, and give great pain when set in motion or touched; the limbs are semiflexed; gastro-intestinal catarrh, with red and somewhat dry tongue; when the swelling of the face has subsided, the feet, legs, and thighs become œdematous, and soon after anasarca over the trunk ensues. There is no other disease in which this particular combination of symptoms occurs.[1]

Cysts containing a black tenacious matter are occasionally found in muscles; they probably are of the nature of hematoma occurring in other parts of the body, being merely unabsorbed extravasated blood, which has become darkened and inspissated by time. Warren describes a singular tumor somewhat of this nature. A tumor about the size of an egg was removed from the substance of the rectus femoris muscle of a woman; it was said to be of only five or six months' growth; it consisted of a hard dark-colored muscular substance, in the centre of which was a bony shell an inch in diameter, containing a dark-colored fluid, which had deposited a black crust on the bony cyst.

Vascular tumors are not very frequently found in the substance of muscles. According to Mr. Campbell De Morgan,[1] they occur under three forms. 1. As tumors having the appearance of a varicose state of the veins, unconnected with the muscular tissue in which they lie, but yet not isolated by any well-defined covering of connective tissue. 2. As erectile tissue, forming in, and encroaching on, the muscular fibres, from which it is not separated by any defined boundary. 3. As erectile tissue, forming a defined tumor, having an investment of connective tissue not continuous with the muscular substance in which it is embedded.

The disease is most frequently congenital, but may come on later in life, after injury, or without any assignable cause. It is more commonly seated in the muscles of the lower extremities. The origin, mode of growth, and true structure have not yet been satisfactorily ascertained; but it either spreads through the muscular tissue or occurs in the form of isolated tumors. The muscular fibres on which it encroaches are compressed by the hypertrophied vascular and connective tissues, and their nutrition being impaired by the altered and thickened state of the capillaries, they degenerate to a greater or less extent, and become transformed for the most part into fat, while the connective tissue increases in quantity, and is in some places condensed into masses or bands, which, when they form at the circumference of the tumor, constitute its fibrous sheath. There appears, also, to be an increase in the quantity of yellow elastic tissue. The changes which occur in the vascular tissue itself are not well understood.

---

[1] For a recent and elaborate description of the nature and treatment of trichinosis, see a paper by Dr. Thudichum in the Seventh Report of the Medical Officer of the Privy Council, 1864. Also a shorter paper by Dr. Althaus, in the Medical Times and Gazette, 1864.

[1] British and Foreign Medico-Chirurgical Review, 1864, p. 187.

Sometimes the disease shows itself in a number of different places in the same subject, as in cases recorded by Cruveilhier; in one of these the hand and arm were covered with innumerable small tumors, varying in size from that of a small shot to that of a large bean. They were all composed of erectile tissue. It is generally allowed that vascular tumors are very prone to degenerate into cancer.

Scirrhus seldom originates in muscles, except in the tongue and substance of the lip. [It is very doubtful if any form of cancer ever originates in muscle; and the cases referred to in this and the succeeding paragraphs, as those of melanotic and encephaloid carcinoma, were in all probability of sarcomatous nature.] Warren describes a case of what he terms scirrhus of the muscle, which resembles more the account given of the syphilitic tumor described as having been removed from the shoulder by Mr. South. Muscles readily become implicated in the disease occurring in neighboring parts, and it is not unusual to find the muscles for a considerable distance around a scirrhous breast dotted with scirrhous tubercles. Melanosis must be very rare in muscles. Warren mentions a case occurring in the muscular structure between the base of the scapula and the spine; this had been removed, but a second tumor appeared in its place under the cicatrix; it was found, on operating on it, to be seated in the substance of the rhomboid and trapezius muscles; it was hard in structure, and the interior composed of black matter; six months after this, the disease reappeared, of a carcinomatous appearance, and proved fatal.

Encephaloid tumors no doubt originate in muscles, though they grow so rapidly, and involve every structure so indiscriminately, as to make it difficult, except in certain organs, to define their origin. Warren, speaking of this disease in muscles, describes three cases. These, however, are not clearly proved to have sprung from muscle, except the last, which had its seat in the lumbar muscles.

AFFECTIONS OF TENDONS.

Injuries of tendons.—It has been already observed that tendons are ruptured by the action of their muscles more readily than the muscles themselves; they may also be ruptured by direct force, as in dislocation, and they are often divided partially or entirely in wounds, and by subcutaneous sections. When a tendon is ruptured, or, what is nearly the same thing, divided by subcutaneous operation, the part which is attached to the muscle is drawn away from the opposite end for about an inch; this latter is but slightly retracted by the action of its antagonists. Blood is poured out between the ends, but much less than in rupture of muscles. The pain is said to be not very great; a considerable shock, however, is felt, as from a blow received on the part, accompanied by cramp of the muscle, and a perfect inability to use the limb; and in rupture of the tendo Achillis a feeling is described as if the heel were sinking into a hole in the floor. The tendons most frequently ruptured are the tendo Achillis, and the tendons of the rectus femoris and the triceps humeri. If the separation of the ends be not too great, either in rupture or subcutaneous division, they unite with much readiness, the new material soon acquiring great firmness. So rapidly is the process of repair carried on, especially in the early stage, that, according to Mr. Paget, in his sixth lecture at the College of Surgeons, a specimen six days after division (being the fourth occupied in the organizing of the new structure) could bear the weight of twenty-five pounds; in another case the new material at the end of twenty-one days bore a weight of fifty-six pounds. The process of repair is briefly this, according to Mr. Paget (loc. cit.). For the first forty-eight hours inflammatory matter is poured out, and infiltrates the tissues between the ends; after this there ensues infiltration of a material of the character of the fibrin of the blood in a solid state, in which are enclosed the unabsorbed remains of the clot of extravasated blood, and the two ends of the divided tendon; this by degrees assumes a definite cord-like form; but even in five or six days it shows a nucleated structure, tending to the production of tendinous tissue. On the tenth day, the material becomes paler and less vascular, and assumes a distinctly filamentary form; and in about three weeks there is a perfect cord, of the nature of tendon. Mr. Paget goes on to remark, that in the further stage of the process the ends of the tendon swell and soften to the consistence of the effused matter, so that they may merge one into the other, assuming thereby a closer adhesion. He also remarks, that the repair of the tendon does not depend on the non-division of its sheath, as has been supposed. Should the interval between the two ends of a divided tendon be great, a very imperfect bond of union will be established between them, as the end will become attached to the neighboring tissues, and either a partial or entire loss of the use of the muscle will result. Where the integuments and surrounding parts are included in a division of a tendon, there is, as in muscle, a much greater retraction than where these parts remain entire; added to which, the material for the repair of the tendon being here common to all the other tissues included in the wound, they all become fused in a common cicatrix, so that under the most favorable circumstances a very imperfect union and limited use of the muscle ensue.

The treatment of ruptured tendon consists, as in rupture of muscle, in approximating the divided ends, and retaining them in that position until firm union is established. Close adaptation cannot be hoped for, but still a perfect union with recovery of the action of the muscle usually takes place. The severed ends are brought closer and closer toward one another by the contraction of the new material as it becomes perfected, and the remaining deficiency is fully compensated for by the accommodating nature of the muscle. If the tendon of the triceps be torn, all that is required is a bandage from above downward, with a splint in front of the arm to keep it extended: and as the union of tendon is rapid, passive motion may be employed early. In rupture of the tendon of the quadriceps extensor cruris, the same treatment nearly may be adopted as for a fractured patella. Where the tendo Achillis is torn across, the treatment consists in keeping the foot extended on the leg, and the leg bent on the thigh; a position favorable to the relaxation of the gastrocnemii muscles. For this purpose a belt is placed round the thigh a little above the knee, the back of which is attached to the heel of a slipper by means of a belt or bar. Before applying the instrument, the calf of the leg should be bandaged from above downward, care being taken not to approach too near the seat of rupture, for a great displacement and permanent defect would result from the ends of the tendon being pressed towards the bones of the leg; somewhat of a similar inconvenience may occur from a too considerable or a too long-continued tilting up of the heel. Desault, to avoid the displacement of the tendon by his bandage, which, like Petit's, extended over the whole limb, recommends compresses at the sides of the tendon. John Hunter, who himself had a rupture of the tendo Achillis, recommends that, as so little inconvenience attends a small separation of the tendon, compared to the great inconvenience and difficulties attending the treatment by bandages and straps, the parts should be allowed to remain in their natural position. He is, however, disposed to adopt a medium between the two, and suggests that the heel should be elevated during walking, by raising the heel of the shoe; that a bandage should be kept steadily applied to the calf of the leg, to guard against involuntary actions of the muscles; and that at night the usual slipper and strap might be applied. When the integuments and surrounding parts are included in the division of a tendon, the edges of the wound may be brought together by adhesive plaster, or perhaps by sutures. The mode of bringing the divided ends of the tendon together by means of sutures can scarcely be recommended, as they produce irritation, and keep the wound open. Bandages are not well borne; rest, therefore, with position, must mostly be trusted to for the cure.

[The immovable dressing has been very successfully employed in the treatment of ruptured tendon. Few surgeons at the present day will agree with the author in saying that the use of sutures "can scarcely be recommended," as in many recorded cases complete recovery has followed their employment, and not so very seldom satisfactory results have been secured by attaching the lower end of the damaged tendon to an adjoining tendon.]

Inflammation of tendons.—Tendons, together with their sheaths, both fibrous and synovial, are not unfrequently inflamed. Independently of gout and rheumatism, the most frequent cause is a sprain or wrench in the neighborhood of a joint. These injuries are occasionally productive of long-continued wearing pains, assuming much of a rheumatic character, and yield, often slowly and unwillingly, to the remedies, both local and general, employed in rheumatism. Sometimes these sprains are followed by inflammation, with great effusion into the sheath and surrounding cellular tissue (especially in the region of the foot and ankle), which, either rapidly in an acute form, or slowly in a chronic form, may extend to the ligaments and periosteum, destroying the joints, and producing caries of the bone.

Under the name of "ténosynite crépitante," the French describe a slight degree of inflammation of the sheaths and investments of the muscles and tendons: it follows long-continued and fatiguing muscular exertion, and for the most part occurs in the muscles of the forearm. I have observed it mostly in the extensor muscles of the thumb as they pass over the radius; it is usually accompanied by considerable pains extending up and down the limb, and a well-marked crepitating or creaking feeling can be felt by grasping the part while the muscles are in action. The treatment consists in complete rest, and stimulating or even vesicating applications. In one of the forms of whitlow, *paronychia tendinosa* of Abernethy,[1] the tendons and their sheaths in the finger and hand are the seat of a severe and often most destructive inflammation, which, though often confined to one finger, not unfrequently extends to the hand and arm, attacking not only the tendons and softer parts, but exposing the bones and disorganizing the joints. It arises from the same causes as the other forms of paronychia, slight wounds, pricks, with or without inoculation of irritating or poisonous matter, and often without any evident cause, though doubtless, depending much on the state of the general health. It begins with severe and throbbing pain on the palmar face of a finger, which extends along the arm, often to the shoulder; it is accompanied by redness and swelling, with great hardness and tension: if not checked, the inflammation proceeds quickly along the front of the finger, and is soon followed by suppuration in the sheath; this at first is in small quantity, and, in consequence of the great hardness and swelling of the part, cannot be detected by the touch; if no relief be afforded, the suppuration quickly proceeds along the sheath, the inflammation and pain are aggravated by the density and unyielding nature of the parts, and are accompanied by much constitutional disturbance; abscesses burst externally from time to time as the disease extends along the sheath, from which fungous granulations spring, the tendon in a sloughy state lying at the bottom. With proper treatment, and in a favorable state of the general health, the progress may be arrested with a greater or less amount of destruction of the parts attacked, and a proportionate deformity. In certain unhealthy states of the system, however, in which the diffuse or erysipelatous form of inflammation prevails, the inflammation and suppuration extend into the palm of the hand behind the palmar fascia, and to the rest of the fingers. The whole hand now presents a highly inflamed appearance, of an erysipelatous nature, with great swelling and tension; nor does the mischief end here, but passing under the transverse ligaments of the wrist, ascends into the forearm, forming large diffuse abscesses among its tendons and muscles; and in the worst cases not only the joints of the finger, but those of the carpus and wrist are destroyed, and the bones denuded and necrosed. The health during this time suffers severely from irritative fever, with gradual prostration of the bodily powers.

---

[1] Lect. xxviii., Lancet, April 29, 1825.

Treatment.—In the very early stage the inflammation may often be arrested by leeches, followed by hot fomentations to soften and relax the hard and unyielding tissues. The hand should be elevated, and an active purgative, with other antiphlogistic measures, prescribed; if relief do not soon follow, but, on the contrary, the continuance of pain and throbbing with increased hardness indicate the extension of the inflammation, if not the formation of pus, no further time must be lost; a free incision must be made along the centre of the finger, and though there may be but very little or no pus in the sheath, yet the division of the tensely strangulated structure, and the escape of blood and serum, afford the greatest relief. By these means all mischief may be arrested, and the finger perfectly restored. On the other hand, the inflammation may proceed along the sheath in spite of the most ready treatment; suppuration may have extended under the palmar fascia; further incisions must then be made; and it will now be found proper to support the powers of the system by a generous diet, stimuli, and tonics. In these cases the tendon will slough, and one or more of the joints will be ankylosed, with such disfiguration as may at a future time require amputation; for a stiff and distorted finger, in almost any condition of life, is very inconvenient as well as unsightly. In the more chronic states, where, notwithstanding free openings having been made in the palm, abscesses burrow about the hand, I have found the best results from pressure with pads of lint soaked in pure liquor plumbi, and a bandage, the powers being supported with tonics, good diet, and stimuli. Where the suppuration extends to the arm, the case is more serious; and if, from the state of the constitution before alluded to, it proceeds to the indiscriminate destruction of the joints, nothing but amputation remains, and even that may not save life.

Mr. Tatum has amputated the forearm twice for this disease; the first case was in a gardener, a patient at St. George's Hospital. He seemed healthy and strong, but the diffuse suppuration extended rapidly along the sheaths to the hand and arm, destroying the joints of the hand and wrist, in spite of every endeavor to arrest the disease; and though amputation was performed before the powers were very much prostrated, it was only by constant attention and active treatment that after a long time the man recovered. The other case was that of a gentleman, aged fifty-five, whom Mr. Tatum attended with the late Mr. B. Cooper and Mr. H. Phillips: he was of a bad habit of body, pale and flabby, with a weak pulse; the suppuration, beginning in the little finger, spread with surprising rapidity along the sheath, quickly involved the other fingers, then the hand and forearm, destroying the joints in its course, in spite of free incisions and whatever could be devised in the way of support. Nothing produced the slightest check to the progress of the inflammation, nor any reaction of the system; it was therefore agreed that the arm should be amputated. Mr. Tatum performed the operation unusually high up in the forearm, with a view to cut through sound parts; but even at this height the knife passed through the extremity of an abscess. No reaction took place after the operation; the stump soon assumed a flabby, half-sloughy state; and after some days the patient sank.

It has been already remarked that tendons, as well as muscles, are the seat of syphilitic enlargements. In one of the cases recorded by Mr. Tatum, the tendinous origin of the sterno-cleido-mastoid was much thickened. M. Bouisson (loc. cit.), describing these swellings, remarks that they are formed by deposit between the fibres, as in muscles. He also relates a case of strabismus from a syphilitic tumor occurring in the tendon of one of the muscles of the eye. M. Lisfranc[1] speaks of certain node-like swellings on the surfaces of tendons, which he calls "nodosités blanches des tendons." Syphilitic enlargements of tendons do not, as in muscles, readily yield to the internal use of the iodide of potassium; they require an active local treatment as well, such as iodine and mercurial ointment, or blisters kept open with mercurial ointment. Swellings of the tendo Achillis occasionally occur without a syphilitic origin. Mr. Tatum has found them in persons who have taken long and fatiguing walks, not having been accustomed to much exertion. These swellings sometimes occur as a simple rounded enlargement in the tendon, and sometimes as an irregular thickening; they are tender when handled, and are sufficiently painful in walking to make the patient limp. These tumors are often troublesome to cure, as they do not readily get well without rest, and the pain and inconvenience are not usually sufficient to induce the patient to lie up; in order, however, to cure them it will generally be found necessary for the patient to lie up, or at all events to avoid using the part, and to apply the local means recommended in syphilitic tumors, as blisters kept open with mercurial ointment, or the emplastrum ammoniaci cum hydrargyro, etc.

Tumors of tendons.—Malignant tumors do not often spring from tendon [such tumors being always sarcomatous]; it offers, on the contrary, like other fibrous structures, a lengthened resistance to their progress. Warren gives the following account of a malignant tumor growing in the substance of tendon: A round and prominent tumor appeared above the patella, three inches in extent, without much pain or sensibility, but causing lameness; it had been growing six months. On cutting down, the fibres of the rectus tendon, which were stretched over the tumor, were separated, exposing a white fungous growth firmer than the ordinary fungous tumor, but breaking in pieces when handled. On removal, it was found to be mixed up with fasciculi of tendinous fibres. It showed no disposition to bleed. This tumor returned after the healing of the wound, and was again removed, when it presented a more decidedly fungoid character, with fewer tendinous fibres. The case terminated fatally, with the formation of tumors within the abdomen. Fibrous tumors occasionally arise in tendinous structure, as in fasciæ, and other parts of a fibrous nature. Small cartilaginous enlargements are often found in the course of tendons, especially those of the hand and foot; they do not grow to a large size, and seldom produce any inconvenience. Small growths, described as tæniophytes by Albers,[1] are sometimes found growing on the surface of tendons near their junction with their muscles; they vary in size from a pin's head to a cherry; they are at first altogether cartilaginous, but as they increase in size calcareous matter is deposited in them, as in the development of bone.

AFFECTIONS OF BURSÆ MUCOSÆ.

The closed synovial bags called bursæ mucosæ are of two kinds; those situated in the subcutaneous cellular tissue, and those connected with tendons. The subcutaneous bursa is formed of cellular membrane that has been exposed to friction and pressure, by which its cells are obliterated and a single cavity formed; it retains, in part, the form of its cellular origin, for even after great distension the interior often presents a sacculated or multilocular appearance. Like cellular membrane it has much of the character of serous membrane, in its ordinary state exhaling a fluid little denser than serum, but assuming, after a time, much of the nature of synovia. The subcutaneous bursæ are numerous,[2] and are either normal or adventitious. The normal occur mostly between the skin and some bony prominence. The adventitious bursæ are formed below corns, bunions, or other accidental callosities, as those arising in talipes on the sides or back of the feet. These sacs are liable to become enlarged from various causes, mostly local, as pressure, friction, or blows, though occasionally constitutional. The bursa in front of the patella is most frequently the seat of enlargement, forming a tumor familiarly known as *the housemaid's knee.* The contents of these enlarged cysts vary much; at first they are distended with a fluid little more dense than serum, gradually acquiring more and more the nature of synovia; it is often mixed with blood, either recent or in a thick grumous state; sometimes there is a dark-brownish adhesive fluid containing cholesterine; occasionally, after long-continued pressure, fibrinous matter is deposited within the sac, something after the manner of an aneurism, which gradually fills up the cavity, forming a tumor of a dense fibrous structure; sometimes it is solid throughout; more frequently there is a central cavity containing a gelatinous fluid. Sometimes the fluid in an enlarged bursa contains numerous bodies, resembling melon-seeds or parboiled rice; these are of a dense, fibrinous nature, and appear to be either the result of broken-up deposit, the portions becoming round and smooth by motion and attrition, or productions from the inner surface of the fibrous deposit, which from the effects of motion and friction become first pedunculated, and then, being detached, fall loose into the fluid of the sac, much in the same way as occurs in the formation of loose cartilages in joints. Inflammation, terminating often in suppuration, sometimes takes place in bursæ mucosæ; we see it occurring in a previously healthy state of the part, after a severe blow or a wound, especially in the bursa over the olecranon; the inflammation runs very high, and is not confined to the sac itself, but, in a diffuse form, extends often over the whole arm, with much swelling, redness, and tension; the pain is great and the constitutional disturbance considerable, and in old people there is sometimes much danger. Pus forms rapidly, not only in the sac but also in the cellular membrane, if not relieved. Enlarged bursæ of the patella are frequently attacked by inflammation and suppuration, and usually there is extensive inflammation of the surrounding cellular structure; and sometimes such large collections of pus are found in the neighborhood of the sac, as led Sir B. Brodie to consider that the suppurating bursa occasionally gave way, and allowed its contents to escape into the cellular membrane. The readiness with which the neighboring cellular membrane is involved in the inflammation of subcutaneous bursæ, is probably due as much to the sameness of their nature as to the continuity of their tissue. Troublesome and burrowing ulcers sometimes remain after these abscesses, and sometimes from undue pressure and neglect of a hardened cyst. The ulcerations are singularly obstinate, sometimes with considerable fungous growths, the skin around being dark and unhealthy, with deep burrowings under the integuments about the knee, and a foul and offensive discharge.

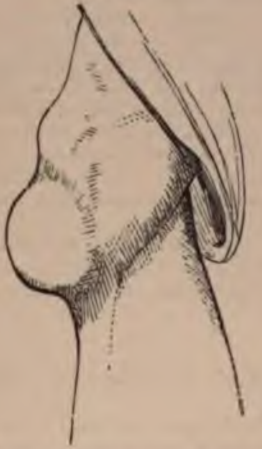
[Fig. 744.



Enlarged bursa over the patella, the result of pressure; housemaid's knee (Liston).

[In many cases of abscess of the præpatellar bursa, the resulting troublesome ulcer is due to imperfect drainage of the abscess-sac, the opening being made simply over the top of the patella instead of at its sides. By making lateral incisions, securing thorough drainage, and immobilizing the knee, a comparatively early and very complete closure of the cavity can usually be secured.]

Treatment.—Whatever treatment may be adopted, it should be accompanied by complete rest. When the bursa over the patella is affected, a well-fitting ham-splint may be applied, and all motions of the knee-joint prevented. Simple enlargement, if recent, will often subside under rest and a slightly stimulating lotion, such as ammoniæ hydrochlorat. ʒj, aquæ ℥v, aceti ℥j, M. Some merely transfix the bursa with a needle, and leave it to itself. If the enlargement has been of some duration, with thickening, more decided measures will be required. Some surgeons evacuate the contents by puncture, and follow it by pressure with a pad and strapping; the sac is likely, however, to fill again, and will require repeated punctures. Counter-irritants often effect a cure, such as the emplastrum ammoniaci cum hydrargyro, or a blister over the part. The iodine ointment or the tincture of iodine applied to the skin over the tumor, may in some cases succeed, especially where the contents have been previously evacuated.

Mr. Key[1] recommends a seton, composed of a few threads of silk, to be passed through the cyst; suppuration is thus set up, and the pus escapes on moving the threads from time to time; compression is also employed by means of a pad and adhesive plaster, the openings being left free. By these means the discharge gradually diminishes, and, partly by contraction and partly by granulation, the cavity becomes obliterated. The French surgeons often treat these cases with iodine injections, like hydrocele. When there is much solid deposit in the sac, Mr. Key still finds the treatment by seton the most effectual; for, considering that the induration is kept up by the irritation of the cavity, the seton, by producing inflammation and suppuration, would cause its obliteration, and the absorbents would remove the indurated walls. When the tumor has become almost or quite a solid, gristly mass, there is no remedy but dissecting it out, which can readily be done without any bad consequences. Where the tumor is very large, and overlaps the patella, care should be taken not to wound the aponeurotic covering of the joint.

In acute inflammation of the bursæ, both local and general antiphlogistic measures are required; but where there is diffuse inflammation around, of an erysipelatous tendency, much benefit is derived from the sesquichloride of iron lotion,[2] with general support. If suppuration has taken place in the sac, it may either be laid open with a free incision, or a seton may be passed through it; the former would be preferable where there is much surrounding inflammation, as it not only gives free exit to the matter, but diminishes tension, relieves the vessels of blood, and the cellular membrane of the effused serum, and often prevents it from running into suppuration. If pus have already formed in the cellular tissue, it will probably be necessary to make one or more incisions for its escape, in as depending a position as possible, and the system will require general support and stimuli.[3]

The bursæ of tendons have more the character of synovial membranes than the subcutaneous bursæ, and are either simple bags containing a lubricating fluid, placed between tendons and prominences of bones, as that between the ligamentum patellæ and the tubercle of the tibia, or complicated with numerous processes and elongations, as in the synovial sheaths of the flexor tendons of the hand and wrist. These, like the subcutaneous bursæ, are liable to enlargement, and often attain a considerable size; but, from their deeper situations, they are less exposed to injuries from without, and consequently do not so frequently inflame and suppurate. The bursa between the ligamentum patellæ and tibia sometimes enlarges and forms a tumor, which, by filling up the depression on each side of the ligament, presents the appearance at first of synovitis of the knee-joint; but the absence of swelling above and around the patella renders the diagnosis easy. Distension of the bursa above the knee usually accompanies synovitis, because this bursa almost always communicates with the joint; this, however, is not always the case, and Mr. Tatum has seen a large bursal tumor under the vasti, the joint being quite healthy. One of the bursæ of the hamstring muscles (usually that of the biceps) occasionally enlarges, and appears in the ham as a pulsating tumor, often of considerable size; it is, however, too little like an aneurism to be mistaken for one by a careful observer. The same may be said of the bursa of the subscapularis, and other bursæ about the shoulder-joint, which sometimes form tumors in the axilla, occasionally pulsating from their vicinity to the artery. The bursa between the psoas and iliacus internus and the capsule of the hip-joint sometimes forms a tumor, which from its situation may be mistaken either for an inguinal aneurism or for a psoas abscess; the extrinsic character of the pulsation and the absence of all other aneurismal symptoms in the one case, and the want of spinal symptoms and of fluctuation above Poupart's ligaments in the other, assist in forming a right diagnosis. This bursa occasionally communicates with the synovial membrane of the joint, and when inflammation occurs in the former, the latter will most likely be involved in it, and serious mischief may follow. The bursa between the gluteus maximus and tuber ischii, that between the tendon of the gluteus medius and the trochanter, and that between the latissimus dorsi and the angle of the scapula, from their exposure to pressure and other sources of irritation and inflammation, are not only liable to inflame, but even to suppurate. When, from frequently recurring pressure in sitting, the already enlarged ischio-gluteal bursa inflames and suppurates, it increases in size, becomes painful, and renders sitting on the part impossible, and even motion distressing; lying deep under the mass of muscle, its fluctuation is obscure, and the suppuration is usually slow in coming to the surface, and after it is evacuated, it often leaves a sinus obstinate and slow to heal, from its depth and the movements of the muscle. The same may be said in most respects of the bursa over the trochanter. The bursa at the angle of the scapula often acquires a great size, and when it suppurates, much constitutional disturbance is often set up. Too much caution cannot be taken in opening these bursæ, whether in their simply enlarged state or in the suppurating stage, as an alarming and even fatal train of symptoms sometimes follows this operation.[1]

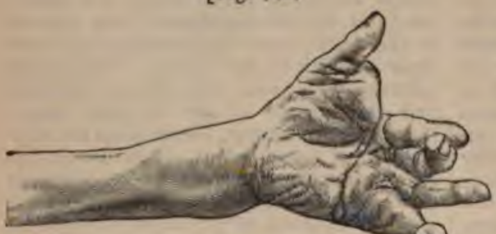
[3] For bunion see SURGICAL AFFECTIONS OF THE SKIN.

The palmar bursal tumor is perhaps the most obstinate of any; forming a swelling under the palmar fascia, it extends under the transverse ligament and ascends into the forearm, presenting a double tumor, the contracted part corresponding with the transverse ligament. The fingers are more or less drawn into the palm of the hand, and cannot be straightened. The fluctuation is readily felt by alternate pressure above and below, and when, which is often the case, the melon-seed bodies are present, a peculiar creaking or grating sensation is communicated to the touch. These bodies are often extremely numerous; Dupuytren believed them to be hydatids, and described their appearance minutely.[2] These tumors, after slight attacks of inflammation, often cease to fluctuate, and become filled with solid, unorganized fibrin; and when inflammation, followed by suppuration, comes on, which it usually does from using the hand in this state, large masses of the coagulated substance may be squeezed out through the opening made to let out the pus; this has been followed by the gradual subsidence of the abscess, and the perfect restoration of the use of the hand. Sometimes, however, the case takes an unfavorable course; diffuse erysipelatous inflammation is set up instead of that of a more plastic nature, and a fatal result will occasionally ensue.

[Fig. 745.



Ganglion involving all the flexor tendons of hand and wrist.]

A patient was admitted under Mr. Tatum's care into St. George's Hospital with disease of this bursa. He was a publican, about fifty years of age, of a stout flabby appearance, with failing pulse; the bursa, which had suppurated, had been opened above and below the wrist, and was discharging large quantities of pus mixed with the rice-like bodies in great numbers; the hand was enormously swelled, and the whole arm, extending above the elbow, enlarged, tense, and of a deep-red color. The case in many respects resembled that of diffuse thecitis formerly described, and, like it, proved fatal, in spite of every means to support the system that Mr. Tatum could employ.

[From the many reports published during the last few years it would seem that by the employment of the "antiseptic method" the danger of operative interference in these cases is reduced to a minimum.]

A modification of the bursa is found connected with the extensor tendons of the fingers and toes; these are termed ganglions; their cavities do not appear to communicate with the sheaths of the tendons, but are formed in the dense tissue investing the sheaths or the capsule of the joint.[1] [In the larger number of cases of ganglia these latter are developed in connection with the tendinous sheath-cavities, though they may communicate with joint-cavities, or arise from the dilatation of mucous bursæ.] They form small, round, movable tumors, rarely larger than a filbert, mostly at the back of the wrist; they are seldom painful, but the patient usually complains of a sense of weakness in the joint. They are found less frequently on the dorsum of the foot; here they present a more compressed form, and are less movable than in the hand. Mr. Tatum has seen them, on the outer part of the dorsum of the foot, more than two inches in diameter, broad and flattened. These cysts contain almost constantly a firm gelatinous substance, nearly as dense as the crystalline lens of the eye. Ganglia do not, like subcutaneous bursæ, arise from pressure; they sometimes follow a sprain, but usually appear without evident cause; they are generally slow in their growth, but now and then appear quite suddenly.

Treatment of enlarged bursæ of tendons.—These bursæ sometimes enlarge rapidly, under which circumstances they subside quickly by rest and evaporating lotions. The more common and chronic form of enlargement requires a more active mode of treatment. Sometimes a blister alone may be sufficient to cause their disappearance; this will be more effectual if the cyst has been previously emptied by puncture; and it may be advisable to keep the blister open. Compression after evacuation of the cyst may succeed in some cases. If they prove obstinate, they may be treated like a hydrocele, by injection of equal parts of tincture of iodine and water; this, however, should not be done in those bursæ which occasionally communicate with joints, nor perhaps in the bursa between the latissimus dorsi and scapula, for reasons already given. A seton often answers well, as in subcutaneous bursæ. The palmar bursa, when enlarged, as well as that at the angle of the scapula, requires some consideration as regards the health, powers, and condition of the patient before active measures are adopted for curing it; for it must be remembered that these measures effect a cure by setting up an active inflammation and suppuration; and it has been already seen how prone the inflammation is to take on a diffuse and most unfavorable form, especially where the bursæ are extensive. Where the tumor is not of long standing, it may often be much diminished, if not cured, by puncturing it, which may be followed by either compression or blisters. In a patient under Mr. Tatum's care with inflamed thecal bursa (a nurse in the hospital), blisters were kept open for some time; after two or three successive punctures the tumors were much diminished and felt solid, the cyst containing evidently coagulated fibrin alone; she was now enabled to use the hand and attend to her duties. At the end of a few months, however, the hand became painful and inflamed, and fluctuation was perceptible both above and below the transverse ligament; an opening was made in each part, and a small quantity of pus escaped, mixed with fragments of coagulated fibrin. Seeing this, Mr. Tatum enlarged the opening and squeezed out a large quantity of very firm straw-colored coagulum; the cysts being emptied, a poultice was applied, and a generous diet ordered. Considerable discharge took place for some days, but gradually diminished; the wounds healed, and so complete was the recovery, that but for the marks of the incisions, no signs of previous disease existed. It has been recommended to lay open the entire sac, dividing the transverse ligament, and dressing the wound to the bottom with lint. This treatment one would hardly recommend, though where the rice-like bodies exist, simple punctures will not give exit to them, and incisions must be made for the purpose. In some cases both the seton and iodine injections may be employed, but with extreme caution. The ganglion may be treated in various ways; it is apt, however, to return. If the walls are not very dense, the sac may be ruptured by firmly compressing it with the two thumbs, or it may be divided subcutaneously with a tenotomy knife, or punctured with a grooved needle, and the crystalline contents squeezed out. Whichever plan is adopted, the swelling will probably return, unless further means be employed, such as firm compression with a small solid body tightly bandaged over the part; or a blister may be applied over the part with a good effect. Boyer (loc. cit.) has described a case of very extensive ganglion connected with the extensor tendons of the fingers, which he dissected out and dressed to the bottom with lint, having previously failed in the treatment by seton and compression. The result of the operation was very favorable. These cysts, however, cannot be entirely removed by operation; the attached parts cannot be dissected from the tendon or ligament; so that they will return unless the wound be kept open to the last.

NERVE-LESIONS AND THEIR MORE IMMEDIATE EFFECTS.

By J. Lockhart Clarke, M.D.

Revised by Roberts Bartholow, M.D., LL.D.

Diseases of Nerves.

Nerves are subject to as many disorders and injuries as most of the other tissues of the body. They are liable to inflammation, suppuration, ulceration, and gangrene; to atrophy and enlargement; to softening and induration; to the formation of cysts, fibrous or neuromatous tumors, and cancerous growths along their course; to compression or stretching; to contusions, lacerations, punctures, and partial or complete division.

Inflammation of Nerves.

Inflammation of nerves is less common than that of most other soft tissues. It attacks in preference the sanguine and robust, and adults rather than children, in whom neuritis is rare. It may be either acute or chronic, and either idiopathic or traumatic.

Acute neuritis is generally preceded by the usual prodromata of inflammation. Its characteristic symptoms consist of a tearing, darting, or lancinating pain along the course of a nerve-trunk or its branches, attended with a sensation of tingling, formication, or numbness, which are sometimes followed by partial or complete paralysis of the muscles supplied by that portion of the nerve which is below the seat of inflammation. The pain never becomes *suddenly* severe or ceases suddenly, or intermits, as in non-inflammatory neuralgia; for although it frequently remits or abates, it is a continuous pain which gradually increases in intensity and gradually subsides. It is always aggravated by pressure on the inflamed portion of the nerve, by contraction of the muscles to which it distributes branches, or even by the slightest touch along its peripheral course; while, on the other hand, it is relieved by firm pressure above the seat of inflammation. Sometimes the nerve is swollen at the part affected, resembling a cord stretched along the surface of the limb. Usually the movements of the limb are much impaired, and there is often a convulsive agitation of its muscles. The pulse is frequently strong and quick, the temperature of the skin over the inflamed part is much increased, and there is generally a variable degree of sympathetic fever, in proportion to the size of the affected nerve and the intensity of the inflammation.

[As regards the symptomatic expression, the results of inflammation of nerves differ in sensory, motor, and mixed, or compound nerves. The symptoms also vary according to the stage of the disease and the extent of the mischief. When the sensory nerve is involved, pain in the peripheral expansion of the nerve is the most pronounced symptom, and alterations of nutrition may follow. The pain varies from a mere sense of soreness to an excruciating agony; but as is the case with non-inflammatory nerve-pain, the suffering is not always at the maximum, but is rather paroxysmal. If the inflammation proceeds to the destruction of the nerve, the peripheral pain ceases, or is not recognized by consciousness, and anæsthesia and analgesia are substituted. When neuritis involves a motor nerve, instead of pain, muscular rigidity or spasm results. All of the muscles innervated by the affected nerve are thrown into a state of forced flexion, extension, or merely spastic rigidity. If the inflammation proceeds to the destruction of the nerve, the symptoms of irritation give place to those of loss of function; in other words, paralysis succeeds to spasm. In the case of neuritis involving a mixed nerve, both sensibility and motility are affected; at first, the symptoms are those of irritation—pain and spasm; afterwards, anæsthesia and analgesia, paresis and paralysis, indicate the destruction of the nerve.

Neuritis manifests a tendency to spread from its original site in both directions—*neuritis ascendens, neuritis descendens.* The centripetal extension takes place strictly by contiguity of tissue, or by metastasis, and ultimately the spinal cord may be reached and its anatomical elements injured to a less or greater extent.

Very important trophic alterations occur in some cases of neuritis. Conjunctivitis, ulceration of the cornea, staphyloma, etc., are caused by an inflammation of the ophthalmic division of the fifth nerve. Herpes zoster, destructive ulceration of the skin, disease and deformity of joints, etc., succeed to inflammation of the peripheral nerves in various situations.

Besides these immediate effects, various reflex and remote disturbances ensue. Irradiations of pain occur, especially upwards and by means of the associated plexus of nerves, and muscular spasm and paresis in distant muscular groups, are produced by a reflex influence.

The electrical reactions of the affected nerves afford precise indications of their condition. When the stage of hyperæmia comes on, the electrical response of the nerves, both sensory and motor, is more ready than in the normal state. As the inflammation proceeds and the nerve elements are disassociated and destroyed, there ensues a quantitative decline in the reactions to both forms of the current. With the progress of the motor nerve changes, alterations of a peculiar kind occur in the muscles, and are now known as the "reactions of degeneration." Further on, these will be described with some detail.]

The seat of inflammation in neuritis is the neurilemma and the connective tissue between the bundles of fibres; and whatever changes the fibres may undergo are the consequences of deranged nutrition. When the inflammation has been of moderate intensity and not of long duration, the nerve has been found to be more or less altered in color, varying from a pale rose to a deep red, according to the greater or less amount of vascularity in the neurilemma and interfibrillar connective tissue. For the same reason, also, there is a variable increase in the diameter of the nerve, its component bundles being separated from each other more widely than usual; but the fibres retain their natural structure, or at least do not appear to have suffered any remarkable change.

The inflammation may either terminate in resolution or reach its greatest intensity. In the latter case, the nerve is extremely vascular and of the deepest or violet red throughout its entire thickness. Its volume is still further augmented, sometimes to twice or even three times its natural diameter. This is the result partly of the increased hyperæmia, and partly of the inflammatory products that are poured out. These products consist of sero-fibrinous or sero-sanguinolent fluids; of pure blood, or blood mixed with pus, infiltrated into the neurilemma and between the bundles of the nerve-fibres, which undergo disintegration or degeneration, in consequence of impaired nutrition. Sometimes the nerve is softened and easily torn, or even reduced to a pulp; at other times it is indurated and tense, from coagulation and hardening of fibrinous exudation. In some cases it is interspersed with minute ecchymoses, or with hard grains along its inflamed course; in other cases it is covered with small abscesses, or enveloped in pus or puro-sanguinolent fluids, or fibrinous exudation; or it contracts adhesions to contiguous parts.

Chronic neuritis may either result from incomplete resolution of acute inflammation, or be the continuation of a milder form. In either case it is a frequent cause of certain kinds of neuralgia, of neuroma, and of painful subcutaneous tubercle. Its morbid anatomy consists of an increased vascularity of the affected nerve; sometimes of a varicose state of its bloodvessels; of a thickening and induration of the neurilemma, in consequence of coagulable exudations. In a variable degree the nerve assumes a somewhat slate color, loses its characteristic opacity, and when examined under the microscope, the nerve-fibres are found to have fallen, to a greater or lesser extent, into a state of disintegration.

[In acute neuritis, the nerve-fasciculi are bathed in a serous or fibrinous exudation. On microscopical examination, besides a more or less intense hyperæmia, in the neurilemma are seen leucocytes floating in serum, and the medulla of the nerve-fibres is beginning to disintegrate. Suppuration next occurs, the nerve elements are disassociated and softened, the axis cylinder then disappears, and finally nothing remains but a brownish, or chocolate-colored, diffluent mass. When recovery occurs, the inflammation being less intense and destructive, the hyperæmia disappears, the liquid portion of the exudation is taken up, the solid matters undergo a fatty degeneration and are emulsionized, and slowly the nerve-fibres are restored. The process is different when the inflammation is chronic in character. Then the tendency is less to suppuration and softening, and more to increase of the connective tissue,—to sclerosis. Sometimes the connective-tissue hyperplasia is uniform, the whole nerve being thickened and indurated for a considerable distance, or the process occurs at particular places, so that the nerve assumes a fusiform or spindle-shape; or, again, it is enlarged at intervals, when it presents a knobbed appearance—*neuritis nodosa*. The inflammation may attack the sheath of the nerve, chiefly, and this contracts adhesions to neighboring tissues, the nerve itself remaining movable although compressed. In other cases the nerve as well as its sheath is the seat of the inflammation; in the growth of the new connective tissue, the proper nerve-elements are compressed, and consequently atrophy and disappear, nothing remaining but a fibrous cord. On microscopic examination, there is but little hyperæmia; the interstices are crowded with leucocytes and granular cells; but the most important change is the overgrowth of the interstitial connective tissue, and the consequent fatty and atrophic degeneration of the nerve-fibres with their axis cylinder. With the injury to the nerve occur the secondary trophic changes, and, if the nerve be motor in function, nuclear growth of the muscular fibres.]

Idiopathic neuritis, although much less common than traumatic, is, I believe, more frequent than it is generally considered to be. Its chief exciting causes are exposure to cold, to damp, and particularly to the combination of both; the suppression of profuse perspiration; the arrest of hemorrhoidal discharges; excessive bodily fatigue; strumous or tubercular affections, and sometimes visceral inflammations and suppurations.

Martinet relates the interesting case of a deserter—an athletic young man, who, after an obstinate chase through a wood, was captured by the gendarmes, covered with sweat, and in a state of wild excitement. On the third day after his capture, he was unable to sustain himself on his legs, and experienced an excruciating pain along the back of his thighs, in the course of the sciatic nerves. Soon after, the patient was attacked with pneumonia, and died on the eighth day of his illness. On post-mortem examination, both sciatic nerves were found to be as thick as the index finger, and hard and resisting. All their component bundles were separated from each other by a sero-sanguinolent fluid, and were penetrated by a multitude of blood-vessels, which imparted to the nerve a deep-red color.[1]—Gendrin mentions the somewhat similar case of a man who walked from Lyons to Paris. During the last two days of his journey, he experienced a dull pain in the course of the right sciatic nerve. The right leg became entirely useless, and the patient died in a fortnight. On examination, the right sciatic nerve was found to be of a deep rose color at one part, and of a deep red at another. It was infiltrated with serous fluid, and three times its natural diameter.[2]—Martinet has recorded nine other cases of idiopathic inflammation of nerves, the most important of which I will very briefly describe.

CASE 1. Violent and continuous pain in the course of the left cubital nerve, without impediment to the muscular movements. The nerve attained the size of the little finger, and appeared like a cord stretched along the arm.

CASE 4. A woman previously in good health began to have pains along the left arm. These pains gradually became violent and extended to the fingers. First weakness, and then paralysis of arm with numbness. A blister to the inner side of the arm brought back the power of movement, which, however, was again lost, with increase of pain, as soon as the blister healed. Eight or ten days later, pain was felt in the opposite arm, but the power of movement remained. After some months, during which her condition varied, she had acute pain in the right *lower* extremity, followed by loss of motion. A slough formed on the sacrum, and death ensued a few days later. On post-mortem examination the spinal cord was found healthy, but the median nerve on the left side, at its separation from the other branches of the brachial plexus, was of a deep red color *throughout its entire thickness*, for about two inches in length. A nearly similar condition was found in the anterior branch of the seventh cervical nerve, which contributes to form the median. The right *sciatic* nerve, enveloped in a large quantity of gangrenous areolar tissue, presented, at its superior part, and for a length of about two inches and a half, a deep brown color through its whole thickness, but without any alteration of either its volume or consistence.[3]

From this interesting case, we learn that nerves situated at a distance from each other may consecutively and independently become affected by idiopathic inflammation.

Mr. Earle,[4] Sir Charles Bell,[5] Barensprung,[6] and others, have recorded interesting cases of idiopathic inflammation of nerves. Barensprung's case was a scrofulous child, one year old, in which both roots of the sixth, seventh, and eighth intercostal nerves were found enlarged and red.—Martinet's eighth case was also a child, twelve years old, who had for some time shown the characteristic symptoms of phthisis, and in whom there was violent inflammation of the left sciatic nerve. The child died in about seven weeks in a complete state of marasmus. On examination, numerous tubercles were found in both lungs, the greater number in a state of suppuration. The left sciatic nerve was not sensibly increased in volume, but the whole of its upper third was embedded in sanious pus, which separated it from the surrounding muscles. The same kind of pus was found between its bundles. This case and the preceding one are particularly interesting from the fact of their occurring in children, in whom neuritis is rare.

Traumatic neuritis is much more common than idiopathic. As the term implies, it is the result of some external injury, such as wounds, contusions, fractures, dislocations, surgical operations, etc. According to my own observations, it is less frequently fatal than the idiopathic form.

Treatment of neuritis.—The most important remedies to be employed in the treatment of *acute* neuritis, are the local abstraction of blood by means of cupping or leeches; evaporating lotions or anodyne fomentations; a spare diet with the use of purgatives; tartarized antimony, opiates, belladonna, and the preparations of aconite. When there is reason to believe that the inflammation is of a gouty, rheumatic, or syphilitic character, colchicum, iodide of potassium, or perhaps mercury, should be employed. In cases where it is complicated with serious internal disease, or associated with a low cachectic condition, the treatment must be modified accordingly.

In *chronic* neuritis repeated blisters along the course of the nerve sometimes afford great relief. Anodyne fomentations, and especially liniments of aconite, belladonna, chloroform, and opium, are frequently of signal service. At the same time attention must be directed to the state of the general health. Vegetable and mineral tonics, iodide of potassium, and mild aperients are sometimes indispensable.

Ulceration of nerves, as a primary affection, appears to be unknown; but nerves in the neighborhood of ulcers are liable to become involved in the morbid process, and then they are generally the cause of intense and protracted suffering.[1] In such cases, the surrounding soft parts are often enlarged, the skin increases in thickness, the muscles and tendons share in the ulceration, and even the bones increase in dimensions. On either side of their ulcerated portion the nerves are generally thickened, sometimes to nearly double their natural diameter.

When these ulcers are exceedingly painful, Mr. Swan recommends the use of ointment made with powdered opium, or lotions made by mixing well-powdered opium with water, or lime-water. These should be applied on lint, and then a folded cloth moistened with water, or laudanum and water, should be placed over the surrounding skin; at the same time the digestive organs should be regulated. When other remedies have failed, and the disease is confined to the soft parts, excision of a portion of the nerve will be advisable, but if the bone be affected by caries or necrosis, amputation may be necessary. Mr. Swan recommends, that in excising a portion of the nerve, the operation should be performed as far as possible from the ulcer, because there is then a much greater probability that the external wound will heal by the first intention, and that consequently the cut ends of the nerve will escape inflammation and ulceration. It is also advisable to divide the nerve as near the upper part of the wound as possible, as the end of the nerve will thus retract from the wound, and consequently be less liable to become inflamed, should the external parts have assumed this disposition.[1]

Tumors of Nerves.

Of all the morbid growths that are found in connection with nerves, tumors are by far the most frequent. They vary considerably both in size and structure, but are commonly a source of acute pain and of the most distressing nervous affections. The smallest kind are known as *painful subcutaneous tubercles;* the larger kind as *neuromata.* The former are either more or less spherical, or oval, or fusiform, and sometimes rather flattened. Their color is generally white, but occasionally there is a brownish tint on their surface or in their interior. They are always firm, sometimes hard, and have a fibrous or fibro-cartilaginous structure. Their size varies from that of a millet-seed to that of a pea or a grain of oat. They are situated in the subcutaneous areolar tissue, and are generally more or less imbedded between the fibres of the nerves, which are separated and stretched over them. Sometimes, also, they have a close connection with a subcutaneous vein in the neighborhood of the nerve. They are generally solitary, and mostly confined to the upper or lower extremities, especially the former. Women are more subject to them than men; of eighteen cases collected by Wood, fourteen were women.

---

[1] Nerves sometimes ulcerate in consequence of the pressure of tumors, etc. A striking case of ulceration of the sciatic nerve, produced by pressure of aneurism, which extended backward from the right groin, is recorded by Morgagni, De causis et sedibus Morborum, epist. 50, p. 11.

[1] Swan, on Diseases of Nerves etc., p. 83, 2d ed.

It is not easy to determine the cause or mode of origin of these tubercles. They appear in many instances to be the result of chronic inflammation, and have been found to follow certain injuries of nerves, especially contusions. When once deposited, they seem to grow with some rapidity, but may then remain stationary for a number of years.

This small subcutaneous tubercle is a source of the most acute pains, which dart like electric shocks along the course of the nerve, sometimes in both a peripheral and central direction. The pains recur very irregularly, and last, at each attack, from ten minutes to two hours or more. They begin gradually, increase in intensity, and gradually decrease, leaving the tubercle and its surrounding parts more or less tender to the touch. They are frequently excited or aggravated by changes in the weather from hot to cold, or the reverse, by storms, etc., and sometimes by mental emotions. The paroxysms may be repeated several times a day, or there may be remissions of days or even weeks. In many instances the tubercle is not tender to the touch except during the attacks, which are much aggravated by pressure.

In all cases of obstinate neuralgia, especially of the extremities, a careful search should be made for the possible existence of tubercles.

Valleix relates the case of a lady who suffered for fourteen years from acute pain in one of her knees, which no kind of treatment succeeded in relieving, until M. Cabaret, on carefully examining the part, discovered a small tubercle about the size of an oat attached to a cutaneous nerve.[1] After its removal the pain entirely ceased.—Marjolin furnished Descot with notes of a remarkable case of painful subcutaneous tubercles of the scrotum. A robust man, thirty years of age, had complained, for more than a year, of sharp, lancinating, and intermitting pains in the right side of the scrotum and inner side of the corresponding thigh. On examination, he found in the areolar tissue immediately beneath the skin of the scrotum, several small, smooth, lenticular, movable, hard, and isolated bodies. When compressed between the fingers, they caused the same kind of pains as the patient was accustomed to feel. A small incision of the skin was made over each of them, and they were easily extracted by compressing the edges of the incision. The operation was followed by a complete cessation of the pains.[1]

Neuroma.—Neuromatous tumors, although they differ from each other considerably in size, are larger than the subcutaneous tubercles, and are more variable in structure. They have been found of every intermediate magnitude between a small grain of wheat or oat and a large melon.

Dr. Smith, of Dublin, found on the left sciatic nerve of a man who died in the Richmond Hospital, a neuromatous tumor which measured ten inches in its transverse, and eleven inches in its long diameter. The fibres of the nerve were separated from each other, and studded with small oblong tumors.[2]

Neuromata are either round, oblong, oval, or fusiform. They are situated either between the neurilemma and the nerves, or in the connective-tissue between bundles of the nerves. In the former case, the bundles, although pressed together and flattened, are not separated from each other; while in the latter case they are spread out, sometimes in a very regular manner, over the surface of the tumor.

In structure they not unfrequently differ from each other to a very considerable degree. The majority, or those of small and moderate size, are generally solid throughout, although not of uniform density. Sometimes they are exceedingly dense, and have a fibro-cartilaginous and glistening appearance, with a yellowish or grayish tint. They consist for the most part of tough and wavy fibrous tissue, in connection with a variable number of nuclei and small cells. In an interesting case of paralysis of the third cerebral nerve with slow hemiplegia of the same side, from supposed syphilitic disease of the brain, under the care of Dr. Hughlings Jackson, a neuroma of the third nerve, among other lesions, was discovered after death. The description which I gave of the structure of this tumor is applicable generally to neuromata of this kind. "On examination under the microscope, it was found to be everywhere composed of a multitude of nuclei, with some nucleated cells, and an abundance of fibrous tissue. Some of the nuclei were more or less oval, but the majority were round, and measured about the $\frac{1}{3500}$

of an inch in diameter. Amongst these were other bodies of the same nature, but of all degrees of smaller size, and either elongated, angular, or in the form of granules. The nucleated *cells* were of very small size, and very granular in structure. A few of them were sparingly scattered through the tissue, but, for the most part, they were collected here and there into small, oval, or circular groups. Between these elementary bodies there was an abundance of ordinary fibrous tissue. The fibres were generally more or less tortuous, but parallel, and in their course each divided again and again into finer filaments, which were connected with the cells and with all the other elementary bodies; the granules and the angular or elongated nuclei filling up the interspaces between those that were oval or round; and thus contributing to form with these and the fibres, a close, uninterrupted, and *reticular* structure."

In other and less numerous kinds of neuroma, the tumor may consist of a single cyst containing a gelatinous fluid, or of a larger mass of ordinary structure containing a number of cysts.[1] Occasionally the tumor has been found to be lobular; the lobules having been connected with branches of the nerve on which the mass was seated, as in a case that will presently be described.

[Neuromata are divided into the true and the false. The *true neuroma* is a neoplasm composed chiefly of nerve-fibres, mixed with connective tissue, and according as nerve-tissue, vessels, or fibrous tissue is predominant, is designated glioneuroma, neuroma teleangiectodes, fibroneuroma, etc. The *false neuromata* consist of fibromata, myxomata, sarcomata, carcinomata, etc. *Fibromata* are, of all neoplasms of nerve, the most frequently encountered. They consist of connective tissue, and have a few nerve-fibres intermingled. They occur as small hard knots on the peripheral nerves, especially on the small cutaneous branches about joints, and are remarkable for the intense pain which attends them, sometimes arising spontaneously and in paroxysms, and again excited by changes in the weather. *Myxomata*, although less common than those just mentioned, are still quite often encountered. They are so named because composed of a soft, gelatinous, and transparent material consisting of branching and intercommunicating stellate cells. This form of tumor also undergoes cystic degeneration, not unfrequently, whence the variety *neuroma cysticum*. The various forms of *sarcomata* occur only rarely in the nerves. They often present a close correspondence in development and in their external characteristics to myxomata. The ordinary varieties of *carcinoma*, also, develop in connection with nerves—either entering them from adjacent parts and extending along the neurilemma, or arising from the nerve-elements themselves.

To these forms of neoplasms should, also, be added *syphilitic gummata*, which usually penetrate the nerves from the cerebral or spinal dura mater. The most frequent site of these gummata is the middle fossa of the skull, the cerebral nerves, originating there or passing through, being invaded.]

Unlike the subcutaneous tubercles, neuromata grow somewhat rapidly, and steadily enlarge, although they are liable to increase and diminish alternately in size. Their number is exceedingly variable. Sometimes they are solitary, one only being found on a nerve-trunk; sometimes several form on the same trunk, or on the same branches of a nerve; and in rarer instances they form on all or nearly all the spinal nerves in the same individual. Dr. Hughes Bennett states, that in the Museum of the Richmond Hospital, Dublin, he examined a most remarkable series of preparations, taken from two individuals in whom almost every nerve of the body presented knotty swellings.[1] In the case already quoted from Dr. Smith, of Dublin, in reference to the enormous neuroma on the sciatic nerve there were also found on the anterior and lateral regions of the right *lower* extremity, no less than 150 tumors, and about 100 on the nerves of the right *upper* extremity.[2] In another case described and figured by Dr. Smith, the abdomen and lower part of the thorax were covered with a vast multitude of small superficial neuromatous tumors, which might easily have been confounded with malignant tubercle.[3]

Neuroma may be either traumatic idiopathic. In the former variety the tumors are caused by wounds, blows, pressure, or by foreign bodies in contact with nerves, or lodged within the They are generally solitary and solid in structure.

The idiopathic variety appears to be the result of several different causes, viz. chronic inflammation, rheumatism, gout syphilis, or some other peculiar constitutional vice. Some pathologists believe that the disease is of the nature of scirrhus, but this opinion is not supported by facts. As in traumatic neuroma, there is generally only one tumor, but in some cases, as already shown, the number may be immensely multiplied.

---

[1] In the Museum of St. George's Hospital (ser. viii., No. 152), there is a preparation showing a cyst on the median nerve of a patient who had suffered the most excruciating pain in the arm.

[1] Dr. Hughes Bennett, Principles and Practice of Medicine, 4th edit., p. 195.

[2] Treatise, plate ii. This is apparently one of the cases mentioned by Dr. H. Bennett.

[3] Treatise, p. 17, plate vi.

When the tumors are very numerous, there is little or no pain; but a solitary neuroma, whether traumatic or idiopathic, is a source of the most violent agony, which shoots along the nerve like sudden electric shocks; the pain is sometimes continuous, but is always aggravated by pressing or touching the tumor, which seems, during the paroxysm, to be in a state of erethism. Mental emotions and atmospheric changes are also not unfrequently the exciting causes of an attack. After the disease has existed for a length of time, the pain, which at first occurred only in paroxysms, may become continuous. In idiopathic neuroma, it is more frequently limited to parts below the tumor, while in the traumatic form it may shoot both upwards and downwards. In a few cases on record, the patients were subject to epileptic convulsions, and in two or three they were cured by removing the tumor.

John Hunter removed from the musculocutaneous nerve one about the size of a hen's egg, over which the fibres of the nerve were spread out.—Sir E. Home removed from the axilla of a Frenchman a hard oval tumor about three inches and a half long, and two inches broad. It was enclosed between fibres of one of the large nerves of the axillary plexus, and was the cause of terrible suffering.—Louis removed from the forearm of a young lady a tumor which made its appearance fourteen years back, as a small hard substance midway between the bend of the arm and the hand. At the time of the operation it had so much increased in size that it extended over the whole front of the forearm, and was about six inches in diameter in the middle. The pains increased in severity in proportion to its growth. On examination after its removal, it was found to consist of several lobes, which were connected by pedicles to branches of the radial nerves, like grapes to their stalks.[1]

The exciting cause and mode of origin of these tumors are often exceedingly obscure; but not unfrequently they may be traced to external injuries, particularly to blows and contusions. Cases of this description are recorded by Sir C. Bell,[2] Dupuytren,[3] and others.

When the neuroma is superficial, the diagnosis is by no means difficult. In general the tumor is movable laterally, but cannot be moved in the direction of the nerve without causing great pain. In most cases the skin which covers it remains unaltered, but when the tumor is very large the cutaneous vessels, especially the veins, are sometimes dilated.

The only effectual remedy for these morbid growths is the knife. The operation may consist either of excision of the tumor, with or without a portion of the nerve, or of amputation of the affected limb. When the neuroma is very intimately connected with the nerve, and there is reason to believe that it cannot be extricated from the nerve without great disturbance or injury, it is better to remove a portion of the nerve with it. With regard to the sciatic nerve, which supplies the whole of the limb, excision of a portion of its length would be attended with serious consequences, and therefore, unless the tumor be confined to that portion of it which forms the posterior tibial nerve, and the peroneal nerve can be saved, it would probably be advisable to amputate the limb.

Tubercle.—Dupuytren and Cruveilhier have spoken of tubercle in nerves, but there appears to be no evidence to prove that it is ever found in this situation as a primary disease; although nerves are sometimes destroyed by the softening of tubercles in which they are involved.

Cancer, unlike tubercle, is frequently met with in nerves, both as a primary and secondary affection. The form of the cancer is in general either the white medullary, or melanosis. It may occur at any part in the course of a nerve, but it is mostly found near its peripheral extremities. It generally grows to a considerable size, as in medullary cancer of the retina. As a secondary disease it is communicated to the nerve by a contiguous cancerous growth.

Dubois, on several occasions, found cancerous growths in the substance of nerves of both the arms and legs.[1] Moutard-Martin saw one on the median nerve, and its removal was followed by cancer of the brain. Dupuytren removed one from the posterior tibial nerve, which, moreover, presented a series of nodulations, like grape-stones. It was the cause of acute lancinating pains. In another case he found the trifacial nerve transformed into encephaloid substance.[2] Cancerous growths have been found, also, on sepaof an inch in diameter. Amongst these were other bodies of the same nature, but of all degrees of smaller size, and either elongated, angular, or in the form of granules. The nucleated *cells* were of very small size, and very granular in structure. A few of them were sparingly scattered through the tissue, but, for the most part, they were collected here and there into small, oval, or circular groups. Between these elementary bodies there was an abundance of ordinary fibrous tissue. The fibres were generally more or less tortuous, but parallel, and in their course each divided again and again into finer filaments, which were connected with the cells and with all the other elementary bodies; the granules and the angular or elongated nuclei filling up the interspaces between those that were oval or round; and thus contributing to form with these and the fibres, a close, uninterrupted, and *reticular* structure."

At the time of the operation it had so much increased in size that it extended over the whole front of the forearm, and was about six inches in diameter in the middle. The pains increased in severity in proportion to its growth. On examination after its removal, it was found to consist of several lobes, which were connected by pedicles to branches of the radial nerves, like grapes to their stalks.[1]

The exciting cause and mode of origin of these tumors are often exceedingly obscure; but not unfrequently they may be traced to external injuries, particularly to blows and contusions. Cases of this description are recorded by Sir C. Bell,[2] Dupuytren,[3] and others.

When the neuroma is superficial, the diagnosis is by no means difficult. In general the tumor is movable laterally, but cannot be moved in the direction of the nerve without causing great pain. In most cases the skin which covers it remains unaltered, but when the tumor is very large the cutaneous vessels, especially the veins, are sometimes dilated.

The only effectual remedy for these morbid growths is the knife. The operation may consist either of excision of the tumor, with or without a portion of the nerve, or of amputation of the affected limb. When the neuroma is very intimately connected with the nerve, and there is reason to believe that it cannot be extricated from the nerve without great disturbance or injury, it is better to remove a portion of the nerve with it. With regard to the sciatic nerve, which supplies the whole of the limb, excision of a portion of its length would be attended with serious consequences, and therefore, unless the tumor be confined to that portion of it which forms the posterior tibial nerve, and the peroneal nerve can be saved, it would probably be advisable to amputate the limb.

Tubercle.—Dupuytren and Cruveilhier have spoken of tubercle in nerves, but there appears to be no evidence to prove that it is ever found in this situation as a primary disease; although nerves are sometimes destroyed by the softening of tubercles in which they are involved.

Cancer, unlike tubercle, is frequently met with in nerves, both as a primary and secondary affection. The form of the cancer is in general either the white medullary, or melanosis. It may occur at any part in the course of a nerve, but it is mostly found near its peripheral extremities. It generally grows to a considerable size, as in medullary cancer of the retina. As a secondary disease it is communicated to the nerve by a contiguous cancerous growth.

Dubois, on several occasions, found cancerous growths in the substance of nerves of both the arms and legs.[1] Moutard-Martin saw one on the median nerve, and its removal was followed by cancer of the brain. Dupuytren removed one from the posterior tibial nerve, which, moreover, presented a series of nodulations, like grape-stones. It was the cause of acute lancinating pains. In another case he found the trifacial nerve transformed into encephaloid substance.[2] Cancerous growths have been found, also, on sepa-

INJURIES OF NERVES.

Contusions of nerves are frequently followed very insidiously by the most serious consequences. If the blow be not very severe, the principal change produced in the nerve is the extravasation of blood and other fluids into the connective tissue between its bundles. There are pain, numbness, tingling, or formication in the parts supplied by its branches, followed, in a greater or less degree, by partial and temporary paralysis, and atrophy of the muscles. If the contusion be very violent, the fibres of the nerve may be lacerated or crushed, and then the atrophy and paralysis are of a much more serious character, and may follow the injury either immediately or not till after an interval of weeks or even months.[2] As we have already seen, tumors are liable to form on nerves that have been contused.

Compression and distension of nerves are frequently the results of a great variety of causes. Of these, dislocation of large joints, and the attempts made at reduction, are among the most common. The effects are more serious in proportion to the length of time before the dislocation is reduced. Sensibility suffers much less than the power of motion. If compression of a nerve be severe and long-continued, it may give rise to incurable paralysis and wasting of muscles. When the injury is not so severe, it causes pain of a more or less acute, and more or less constant, character, attended sometimes with a feeling of numbness or tingling. Nerves may be compressed, also, by aneurisms; by tumors of different kinds formed either upon them, or in their immediate neighborhood; by enlarged glands or bursæ; by abscesses; by cancerous growths; by fecal distension of the rectum and sigmoid flexure of the colon; by hemorrhoids and other causes.

Sir B. Brodie relates the interesting case of a man who had severe pain on the inside of his knee. No marks of disease could be detected in the joint, but in the thigh there was an aneurism of the femoral artery. Sir E. Home applied a ligature round the artery in the upper part of the thigh; the tumor immediately ceased to pulsate, and the pain in the knee ceased also.[1]—The remarkable case related by Morgagni of aneurism of the right groin pressing on the sciatic nerve and producing ulceration with intense pain, has been already quoted.—Scarpa also describes an interesting case of aneurism of the abdominal aorta, causing disorganization of the lumbar nerves and injury to the anterior crural and obturator nerves.[2]

Tumors in the immediate neighborhood of nerves are frequently, by the pressure which they exert, the cause of as much suffering as those which are formed upon them.

Sir B. Brodie mentions the case of a gentleman who suffered severe and increasing pain in the left leg, from the foot to the knee, in the course of the peroneal nerve. As the limb presented no morbid appearance, the disease went by the name of neuralgia. After a considerable time the patient died of dropsy, and on opening the abdomen a large solid tumor was found attached to the left side of the lumbar vertebræ. It was evident that this tumor must have pressed on the origin of the sciatic nerve.[1]—Mr. Travers published an interesting case of compression of nerves by a medullary tumor in the ham;[2] and Sir William Lawrence mentions the case of a tumor in the forearm of a gentleman, situated over the course of the ulnar nerve, and causing exquisite pains, like electric shocks, upwards and downwards, in the direction of the nerve.[3]—Mr. Morris has recorded a most remarkable case of ungovernable satyriasis, excited apparently from pressure on the internal pudic nerve made by a tumor that arose from a blow on the perineum.[4]

[2] Several interesting cases, showing remarkable consequences of contused wounds of the scalp, are recorded by Pouteau, Œuvres posthumes, tome ii.

[1] Works, vol. iii., p. 135.

[2] Treatise on Aneurism, translated by Wishart, p. 99.

Tumors of this description are liable to be mistaken for neuromata, or for those tumors which are formed on nerves or in their substance; but a correct diagnosis may generally be made by moving the tumor in different directions. If the tumor be free, pain will be felt only when it is pressed in the direction of the nerve.

Enlarged glands are not unfrequently the cause of compression and distension of nerves; and there is no nerve so frequently affected in this way as the facial. Several cases of this description were published by Sir Charles Bell.[5]

Sir B. Brodie mentions a case in which "two lymphatic glands, enlarged to the size of large walnuts, were found situated beneath the skin, on the anterior part of the thigh." A considerable branch of the lumbar nerves lay over each of these glands, being thus kept stretched like strings of a violin over its bridge, and giving rise to violent pain and convulsive movements of the leg.[6]

The same author mentions a case of severe neuralgia in the foot, caused by the descent and pressure of internal hemorrhoids, after each evacuation from the bowels.[7]—Romberg calls particular attention to neuralgia of the obturator nerve caused by crural hernia, and gives a long but interesting case in illustration.[8]

Pain of a very acute kind is more often excited by small interstitial growths in nerves than by large tumors over which the nerve-fibres are stretched; for nerves may be stretched to a very considerable extent without exciting any painful sensation, until they become inflamed, or their nutrition be impaired, when the slightest touch causes acute pain. It therefore seems highly probable that the painful effects of compression and distension, by whatever means they may be produced, are in many instances the result of inflammation or of some peculiar kind of irritation which has been excited. When nerves are bruised or otherwise injured at their exit from a foramen or bony canal, they are very liable to cause suffering, because in the event of inflammatory swelling, they are sure to be compressed.

Laceration of nerves occasionally takes place from different kinds of causes, such as accidents by machines, heavy falls, fractures of bones, dislocation of joints and attempts at reducing them. It is somewhat surprising, that, except in parts that are vitally important, laceration of nerves is not followed by serious consequences so often as might be expected.

Béclard has related many cases of this description.[1]—Flaubert mentions a case in which the last four nerves of the brachial plexus were torn from the spinal marrow, by violent extension in attempting to reduce a dislocation of the shoulder-joint. The patient died at the end of eighteen days.[2]—In St. George's Hospital Museum[3] there is a preparation showing the anterior root of one of the cervical nerves torn from the spinal cord, by dislocation of the vertebræ in a heavy fall.

Ligature of nerves.—It sometimes happens that in tying an artery a nerve is accidentally included in the ligature. In certain cases this accident has been followed by severe local and constitutional disturbance, and even by fatal effects. Many instances of tetanus resulting from the same cause, after amputation, have been recorded by several writers. When pain is referred to the amputated limb along the distribution of a particular nerve, there is reason to believe that this nerve has been included in a ligature; and if on pulling at the ligature the pain experienced be aggravated, there can be no longer any doubt as to its cause. Under these circumstances, if tetanus, or any other alarming constitutional disturbance be threatened, the ligature should be immediately removed.

Hennen gives a most interesting account of the effects of ligatures on nerves, in the case of a general officer who suffered amputation of an arm, which was destroyed by a bullet in action. After the occurrence of fever and extensive sloughing, an attempt at clearing the ligatures was attended with the most excruciating pain. "He has," says Dr. Hen-

nen, "frequently, after the smarting of dressing was over, with great accuracy pointed out on my arm the course of the internal cutaneous nerve, as the site of his ideal pain; often he has described that of the external; and on one occasion I, with utter astonishment, had the general neurology of my arm and fingers traced by him. Once only did I ever know him to refer his pain to the sensorium itself. On that occasion, from using an artery forceps to the ligature, on which the slide moved rather stiffly, I exerted a greater force than I intended. He convulsively put his hand to his head, expressed a sense of exquisite pain in his brain, involuntary tears dropped from his eyes, a paralytic contraction momentarily affected his mouth, an universal paleness spread over the uncovered part of his body, and he uttered a piercing cry, exclaiming that the agony of his head and mouth was insufferable. The state of collapse was so great that I was obliged to send an aid-de-camp instantly for volatile alkali and a glass of Madeira, by which he was soon relieved; but the painful sensation and the prostration of his strength continued through the day.[1]

Complete division of nerves.—The effects of complete division, as of other injuries, of nerves, vary considerably in different individuals, according to peculiarity of diathesis, or even in the same individual at different times, according to the state of the general health, and other accidental circumstances. In a healthy person, when the external wound heals kindly by the first intention, no remarkable pain or unusual consequences are experienced. Both portions of the divided nerve retract a little, and their extremities, especially the upper one, enlarge and become more vascular, while coagulable lymph exudes around and between them. In a short time this exudation becomes gradually firmer, and is found to contain cells and nuclei, and then fine nerve-fibres, which proceed from the extremity of the central portion of the nerve to that of the peripheral portion, which, on being separated from its nervous centre, undergoes a gradual atrophy or degeneration. These newly-formed fibres are finer and grayer than those of the central portion of the divided nerve, and it is not till after a period of some months, that they become fully developed. In the mean time a regeneration of fine fibres is going on in the peripheral or atrophied portion of the nerve; but it is a long time before these fibres acquire the normal size and appearance. The same kind of reparative process takes place when a portion of a nerve has been excised, only it occupies a longer period.[2]

When the external wound, instead of healing kindly by the first intention, becomes irritable and inflamed, the ends of the divided nerve participate in the inflammation, and give rise to violent pain, spasmodic contraction of muscles, and other severe symptoms. This is what sometimes occurs after amputation when the stump inflames.

Mr. Langstaff has related an exceedingly interesting and instructive case of this description.[1] After amputation at the forearm in a female, the stump did not unite favorably, and she suffered the most distressing agony, which so affected her health that she became extremely nervous. "There was a constant state of convulsive action of the muscles of the stump. Everything that could be done to improve her health and relieve pain was fairly tried for several months, without the least good effect. She was hysterical, and the paroxysms were frequent." After the stump had healed, a pulsation almost aneurismal could be felt in the situation of the ulnar and radial arteries. Having seen, in several cases, symptoms similar to those caused by the extremities of the nerves becoming ganglionic, and a second operation rendered requisite, Mr. Langstaff removed the arm above the elbow-joint, and previous to securing the arteries, drew out each nerve to the extent of half an inch from the surface of the stump, and cut through them to prevent their interrupting the progress of cicatrization of the integumental parts. The patient was relieved of all her painful sensations, a good stump was made, and her health improved. On examining the amputated part, the median, radial, and ulnar nerves were found remarkably large. The extremities of the two latter were greatly increased by deposition of organized lymph.

Sometimes, after the complete cicatrization of the external wound by which a nerve has been divided, the cicatrix becomes inflamed, and the nerve participating in the inflammation may give rise to the most acute pain, particularly when the part to which it belongs is put in motion. In other cases one or both ends of the divided nerve may be involved in the cicatrix, and be the cause of the most severe suffering. The position of the cicatrix is sometimes important, as when it happens to cross at a right angle the tract of a large nerve which is so related to it as in certain positions of the limb to be pressed against it, causing pain and even loss of motion.

Incomplete division of nerves is, in general, productive of much severer consequences than when the division is complete. If nearly the whole thickness of the nerve be divided, the free portions will retract and put the undivided portion on the stretch; but except in peculiar constitutions, under unfavorable conditions, or when the nerve becomes inflamed, this tension does not in general appear to give rise to serious results. Sir Astley Cooper, in removing a tumor, cut away two-thirds of the thickness of the median nerve. Tingling of the fingers, with some partial numbness, ensued, but nothing more.[1] But partial division of nerves occurring in persons of a peculiarly nervous, irritable, or hysterical constitution, is frequently a cause of the most distressing local and general symptoms.

[2] The process by which divided nerves are reunited has been recently investigated by J. Müller, Stricker, Steinrück, Nasse, Günther, Schiff, and especially Vulpian. (Physiologie générale et comparée du Système nerveux, douzième leçon. 1866.)

[1] Medico-Chirurg. Trans., vol. xvi., p. 140.

Punctures made with different kinds of pointed instruments are the most common instances of this species of injury to nerves. The first symptom which ensues is generally acute pain at the injured part, coming on most frequently at the time of the accident, and darting along the course of the nerves either towards their peripheral extremities or in the opposite direction towards the spinal cord and brain. It is sometimes periodical in its attacks, and attended with redness, tingling, or more or less numbness and swelling of the part. Contractions of the limb, violent spasms or tremors of the muscles, trismus, and even epileptiform convulsions, are not uncommon, and in females hysterical excitement is a frequent consequence. After a time, if the symptoms continue severe, the spirits become depressed, there is more or less prostration of strength, and, in some cases, delirium and coma supervene. The pain is often reflected on to other nerves with which the injured nerve is connected only through the nervous centres, and this sympathetic influence is sometimes experienced to a surprising and terrible extent.

Mr. Wardrop has related the case of a woman who pricked the forefinger of her right hand, near the joint, with a gooseberry thorn. The wound was immediately followed by great pain, swelling and redness, which in a few days extended along the forefinger and adjoining phalanx of the middle finger. At the end of three months the pain and swelling disappeared, except from the two first phalanges of the wounded finger, which remained extremely painful. The patient's general health suffered considerably, and she had severe nervous paroxysms two or three times a day, during which the pain extended along the finger to the back of the hand, and between the two bones of the forearm, darted through the elbow-joint, and up the back of the arm to the neck and head, producing a sensation at the roots of the hairs as if they had become erect. To these symptoms succeeded dimness of sight, and subsequently the pain extended to the stomach, producing nausea and vomiting. She had constantly the feeling of a lump in her stomach, and vomited after taking food or drink. At the end of seven months three incisions were made at the point of the finger, but they gave her no relief. She was afterwards completely cured by amputation of the finger.[1]

A case in which the most violent effects arose from the puncture of a nerve during the operation of bleeding, was related to Mr. Swan by Dr. Wilson, of Grantham. The patient, who was a woman, had been bled by a gardener. On the second day she fell into strong convulsions, and some time after became comatose. The median vein in which she was bled had not healed, and was somewhat inflamed. An incision was made just above the orifice of the vein, when the patient immediately cried out, "I am well; I can stir my arm."

Even fatal effects occasionally follow the puncture of a nerve during the operation of bleeding. Such a case is recorded by Bonetus.[2]

Incised wounds of nerves are frequently the cause of the same kind of symptoms as those produced by puncture.

Hamilton relates the interesting case of a girl, aged seventeen, and of nervous temperament, who, while cutting bread, wounded the septum between the thumb and forefinger of the left hand. The pain from the first was very severe, became still more so, and extended to the thumb, forefinger, back of the hand, up the forearm, inside of the arm to the axilla, shoulder, and side of the neck. These and other symptoms continued for nearly three months after the external wound had healed, when she got a fright in the street, and fell into an hysterical fit. After two days of hysterical symptoms, all pain and swelling left the arm and never returned.[3]

This interesting case is a good illustration of the remarkable influence of hysteria in aggravating the effects of local injuries, and affords an example of the singular manner in which these effects are removed by sudden emotions of the mind. Sir B. Brodie, who paid so much attention to this important subject,[4] justly observes, that when the patients are subject to hysterical paroxysms, sometimes the paroxysms cease on the appearance of the local symptoms, and sometimes, on the contrary, a recurrence of the former is followed by an abatement of the latter, or by complete recovery from them.

---

[1] Lectures, by Tyrrell, vol. iii., p. 171.

[1] Medico-Chirurg. Trans., vol. viii., p. 246. Sir B. Brodie has described a case of the same kind, occurring in a young lady eleven or twelve years of age (Works, vol. iii., p. 170).

[2] Sepulchretum, tom. ii.

[3] Dub. Med. Journ., vol. xiii., case iii., p. 42.

[4] On Local Nervous Affections, and Local Hysterical Affections, Works, vol. iii.

He mentions the case of a young lady, who, having long suffered from hysterical neuralgia of the hip-joint and thigh, was entirely cured of all her symptoms on being thrown from a donkey.

I knew the case of a girl who, while suffering from complete hysterical paraplegia, jumped up in a fright, on seeing a mouse run across the room, and was cured from that moment.

For an important case of incised injury of nerves of which the following is the substance, we are again indebted to Mr. Wardrop.[1] A young gentleman cut the distal phalanx of the left thumb obliquely across the radial side with a gun-flint. The wound readily healed, but on the patient living freely, in a few days the thumb became painful, and although no change in its appearance could be perceived, and the cicatrix seemed perfectly natural, the pain extended to the forefinger, the radial side of the middle finger, and up the arm as far as the neck and side. The pulse was frequent and tense, the face flushed, and the tongue white and frothy. Copious general bleeding gave almost immediate relief. The symptoms, however, returned and yielded to another bleeding, with copious purging. The paroxysms of pain were several times distinctly produced by mental excitement, and on some occasions were brought on by taking even a small portion of animal food. The wounded thumb, which was at all times painful and extremely tender to the touch, was sometimes seized with paroxysms of agonizing pain, which was no longer confined to those fingers supplied by the radial nerve, but extended over the whole hand, arm, neck, and even down the back. Mr. Wardrop divided the injured nerve, with complete abatement of all the symptoms. The success, however, was not permanent, for during several weeks after the operation, whenever he took food of difficult digestion, when purgatives did not readily operate, or when his mind was at all excited, the pain attacked his hand and arm, sometimes severely. After that time he completely recovered. The point of the thumb, however, always remained numb; but whenever the patient's stomach was disordered, he felt pain in the thumb.

This interesting case has several points worthy of particular observation. It affords a good example of acute inflammation excited in a recently injured nerve by a too early use of the part which it supplies, by an incautious mode of living, or by mental excitement. We also see not only that the pain—or rather the irritation exciting the pain—was reflected from the injured nerve to other and even distant nerves with which it is connected only through the medium of the nervous centres, but that even after the connection of the injured portion of the nerve with its nervous centres had been interrupted, pain was still excited in the other nerves by accidental causes. Indeed, in very severe or long-standing cases of traumatic neuralgia, there is reason to believe that the nervous centres in which the injured nerves are implanted, are sometimes secondarily and permanently deranged or diseased, and in this way become the source not only of neuralgia, but even of paralysis in other and distant parts. Among other cases that might be mentioned, one important case of complete division of a nerve, recorded by Mr. Swan, appears to be of this nature.

A young lady, aged twenty-three, on December 20, 1822, wounded the ulnar side of the second finger of the left hand, near the middle of the second phalanx, while cutting an orange. The pain extended to the centre of the left breast, and up the left side of the neck to the face, along the branches of the facial portion of the seventh(?) nerve. On the sixth day after the accident the wound had entirely healed, but was extremely tender. The pain was excruciating when she attempted to move the arm with the hand in a state of pronation. Whenever she read, pain was produced in the superciliary nerves of the left side, after about five minutes. As the patient's health was suffering, on January 11, 1823, Mr. Swan divided the digital nerve near the middle of the first phalanx. She was immediately and completely relieved, and could move her arm in any direction without pain; but, as the effects of the operation was not permanent, on March 5 the finger was amputated at the joint between the metacarpal bone and the first phalanx, and on examining it at the original wound, a small fibril of the digital nerve was found divided; the end of this next the tip was found incorporated with the cicatrix; the other was formed into a small bulb. At the place of the division of the nerve at the first operation, both its extremities were incorporated with the cicatrix, as were those of the dorsal branch, which had also been divided. Although her local and general symptoms were much relieved by the operation, she continued to feel pain in the hand, arm, neck, and face, and, about four months later (in July), she began to complain of her spine. About the end of November she complained very much of pain in her back, with tingling in her arms, and a difficulty of supporting herself erect. Percussion along the spine produced uneasiness in every part, and much pain about the lower dorsal vertebræ. Some time after, she was seized with violent pain in the left knee, which lasted for two or three days. Pressure on each side of the spinous processes of several of the vertebræ produced pain, and percussion with a key made it very severe. She had difficulty in voiding her urine. In October, 1824, she complained of numbness and loss of sensation in the left hip and shoulder, and of pain at the back of the neck, with a feeling as if the neck could not support the head. At the latter end of the year 1825 and beginning of 1826, she was affected by dizziness, in fits of which she fell down, but never entirely lost her consciousness. Her left arm and leg were weaker than the right. When the membrane lining the left external auditory meatus was touched, cough was produced. Up to March, 1829, she had varying degrees of pain and weakness, soreness in the throat, with an appearance of venous congestion and disorder of the digestive organs, with great tenderness in a spot about the size of half-a-crown at the pit of the stomach. She had also some pain and swelling about the uterus and vagina. When sleeping on her left side she very frequently awoke with pain in the amputated finger. Tic douloureux was brought on by either exciting or depressing emotions, by exposure to strong light, and by fits of sneezing, with which she was frequently troubled. When Mr. Swan last saw her, on October 30, 1833, she was nearly in the same state as she had been in for a long time; but we are left in ignorance of the subsequent course of the disease. The patient's father had a paralytic attack.[1]

---

[1] Med.-Chir. Trans., vol. xii., p. 205.

Here, then, we have an instance of very extensive neuralgia, of incomplete but extensive paralysis, and other severe symptoms, extending through a period of ten years, as the effects of simple division of a nerve of one of the fingers. That these morbid symptoms arose out of some peculiarity of constitution, there can be no doubt; and it seems highly probable that this peculiarity was of an hysterical character.

Foreign bodies imbedded in a nerve or pressing against it are often the exciting cause of violent pains and other symptoms similar to those which result from wounds.

Jeffries relates the case of a girl who suffered from violent and almost continual neuralgia of the face for fourteen years. A hard, pointed substance was felt under the skin of the right cheek, and at this point the slightest touch brought on an attack of pain. An incision was made, and a triangular piece of a china cup removed, with complete cessation of the neuralgia.

One of the most interesting and remarkable cases of this description is related by Denmark.[2] A young soldier was wounded by a musket-ball, which entered the triceps extensor cubiti, about one inch and a half above the inner condyle of the os humeri, grazing the inner side of that bone, and passed obliquely downward through the brachialis internus, and out anteriorly through the bend of the arm. The wound soon healed without exciting any particular morbid symptoms. The man was subsequently admitted into Haslar Hospital, with excessive pain, frightful dreams, and startings. The forearm was always bent and in the supine posture. A small tumor could be felt in the site of the wound on the anterior part of the arm, which he could not bear to be touched. The pain began at the extremities of the thumb and all the fingers except the little one, and extended up the arm to the part wounded. It was a burning pain, and so violent as to cause a continual perspiration from the face. Neither opium nor any other means employed assuaged his intense sufferings. At his own request, the arm was amputated, with immediate relief, and he was discharged cured in three weeks. On examining the amputated arm, the radial nerve seemed to be blended with, and intimately attached to, the wounded parts for the space of an inch. It had itself been wounded, and, at the place of the injury, was thickened to twice its natural diameter, and seemed as if contracted in its length. On further examination, Dr. Denmark was surprised to find, on dividing the fibres on the posterior part of the wounded nerve, that there was a small portion of the ball firmly imbedded in it, which had been driven off by grazing the bone.

Treatment of injuries of nerves.—When an incised or other open wound is accompanied and followed by very acute pain, by more or less numbness, and by partial or complete loss of sensation and motion in the part beyond the wound, we may conclude that a nerve has been either injured or divided. Under these circumstances it is of primary importance to remove all dirt or other foreign bodies that may be present, to promote healing by the first intention, and to enjoin perfect rest. If these precautions are not adopted, and the external wound inflames, the nerve is liable to participate in the inflammation, and may then become the source of the violent and distressing symptoms already described. When this is the case it may be necessary to apply leeches to the neighborhood of the wound, to use either cold lotions or warm fomentations of poppies, and poultices, and to act briskly on the bowels by means of purgatives. When the inflammatory symptoms run high and the constitutional disturbance is considerable, I have seen the most decided benefit derived from a combination of tartarized antimony, opium, and hyoscyamus, given at short intervals, the antimony being in sufficient quantity to keep up a state of great nausea.

In some cases, after all inflammatory action has subsided and the external wound has completely healed, painful and distressing symptoms may still persist at intervals for a very considerable period;

---

[1] Swan, Diseases, etc., of Nerves, 2d edit., p. 129. Of this remarkable case I have given the briefest possible abstract of the most salient and important points, but the details, which are very full, deserve attention.

[2] Med.-Chirurg. Trans., vol. iv., p. 48.

and in other cases where the external wound has healed at once in the kindliest manner by the first intention, similar symptoms may supervene. Most of these latter cases are females of a more or less hysterical constitution. But, as we have already seen, there are other causes besides hysteria, such as pressure, dragging, or inflammation of a cicatrix; a premature use of the limb—that is, before the nerve is sufficiently repaired or united; and while the nerve is in this state, it is in some cases very susceptible of irritation by errors in diet, intemperate habits, mental emotions and influences of the most trivial nature. One part of the treatment will of course consist in avoiding or removing the exciting cause, if this can be ascertained. When the cicatrix presses on the nerve, active frictions with moderate exercise of the part will relieve the pain. If it be simply painful or tender, the application of belladonna will frequently allay the irritation; or if it appears to be inflamed, the removal of a little blood by means of two or three leeches may be necessary. If pain and tenderness be experienced in the course of the nerve, repeated leeching, or blistering, and sometimes actual cautery will afford relief. In cases of that intense *burning* pain which is sometimes so agonizing in nerve-wounds, there is no treatment so successful as repeated blistering. The painful state of the parts to which the wounded nerve is distributed may be treated by the local application of anodynes, such as chloroform, aconite, opium, and belladonna; and the most effectual mode of using the two latter substances is by subcutaneous injection. Mr. Pearson[1] has recorded a very remarkable case of neuralgia, which, after resisting every kind of treatment, yielded at length to the application of a stimulating embrocation that was rubbed into the part for ten minutes twice or three times a day.[2]

In some instances when every other remedy has failed, the happiest effects have resulted from the use of mercury exhibited for a period sufficiently long to affect the gums. Mr. Hamilton has recorded two cases of this description.[3] In many instances, however, in which this remedy has been employed, it has completely failed.

In extreme cases, when all other resources are exhausted, it becomes a question whether the nerve should be divided or a portion of it excised, or whether the member which it supplies should be amputated. If the constitutional disturbance be of an alarming character, there should be no hesitation in at once dividing the nerve, or excising a small portion; for these operations have been frequently followed by an immediate arrest of all the symptoms, as in Dr. Wilson's case already mentioned.[1]

In a case of contused thumb followed by violent symptoms, Sir Astley Cooper removed five-eighths of an inch of the radial nerve with complete success.—Mr. Sherwin relates the case of a servant-maid who suffered from the most alarming symptoms after the operation of venesection. At the end of a fortnight she was cured by a deep incision above the cicatrix.[2]—A similar case with the same result is recorded by Dr. Watson.[3] Mr. Earle excised about half an inch of the radial nerve for punctured wound of the thumb followed by pain, spasm, temporary trismus, etc., which had lasted for two months. The patient was soon relieved, and after some months completely cured.

In many instances in which division of the nerve has failed, amputation has been performed with complete success, as in the case of Mr. Wardrop.[4] A still more decided example is recorded by Mr. George Bell.[5] A lady, twenty-six years of age, while cutting a loaf of bread, injured the nerve of the thumb on the radial side. The wound healed kindly, but was followed by excruciating pain and other violent symptoms. Two years after, on two different occasions, an incision was made through the soft parts to the bone, in the neighborhood of the wound, but with only temporary relief. Mr. Bell removed the thumb at the second joint, and in five or six weeks she was restored to perfect health.

However, in some cases, especially of females of marked hysterical constitution, neither the division of nerves nor amputation is of any permanent benefit; while in others which have resisted every kind of treatment except by operation, a spontaneous cure has occasionally been effected.

When nerves have been contused or compressed, without becoming inflamed, the best kind of treatment consists of the repeated use of exceedingly hot fomentations, frictions with stimulating embrocations, and faradization. But if tenderness and pain be felt in the course of the injured portion of the nerve, it will be necessary to apply leeches, cold lotions, and blisters, and to insist on perfect rest.

[The treatment of injuries of nerves includes the measures necessary for the relief of the nerve injured, and the immediate and remote consequences of the injury. For the inflammatory action, involving nerves, there is no treatment more effective than the hypodermatic injection of morphia and atropia, or the stomachal administration of quinia and morphia. If the febrile reaction is at all pronounced, tincture of aconite may be administered with advantage. Blistering along the trajectory of the nerve, and the application of morphia to the blistered surface, is highly serviceable after the more acute symptoms have subsided. To these remedies may be added inunctions of oleate of mercury and morphia, ointment of aconitia, etc. There can now be no possible doubt in regard to the power of galvanism to relieve pain, to lessen inflammatory action, and to cause absorption of the products of inflammation, in parts superficially placed. In cases of nerve-inflammation, so situated as to be readily reached by the current, the pain and spasm are relieved by descending stabile applications of moderate current-strength in recent cases, and of strong currents in old cases. Even more important are the applications of electricity in the treatment of the degenerative changes occurring in muscles in cases of disease of motor nerves. For the condition of spasm and rigidity of muscles, the continuous, or descending stabile current, for wasting and paralysis, the interrupted galvanic or faradic currents are required. For the condition known as the "reactions of degeneration" the form of current used is determined by the power of response possessed by the muscles.]

NEURALGIA.

It has been already seen that a large proportion of neuralgic cases are due to traumatic irritation or inflammation; that some are the result of idiopathic inflammation, in either an acute or chronic form; that others are the consequence of ulceration; of compression and irritation caused by aneurisms, by enlarged glands, by tumors, etc., either in the neighborhood of nerves or in their substance. Moreover, neuralgia of the trifacial nerve has in some cases been found to depend on disease of the bones of the head and face. In the case of the late Dr. Pemberton, the frontal bone was thickened, and in the falx cerebri there was an osseous concretion.[1] Sir H. Halford found hypertrophy and other morbid states of the cranial and facial bones, such as exfoliations of the antrum, considerable thickening of the frontal, ethmoid, and sphenoid bones. Dr. Bright relates an interesting case of facial neuralgia in which he found fungoid tumors of the brain and disease of the cranial bones.[1] In some instances the disease of the bone is the result of syphilis, which also attacks the nerves themselves, not only in the head but in all other parts of the body.

Many cases of neuralgia have a gouty or rheumatic origin; but there are others that do not depend on any of the causes above mentioned, and in which, when there has been an opportunity of post-mortem examination, no appreciable alteration has been discovered in the nerves. Yet that some peculiar, but perhaps only periodical, change takes place in the tissue either of the nerve itself or of the nervous centre from which it arises, there can be no question; for to speak of functional disorder without some material change, is to speak of an effect without a cause. In some instances, the exciting cause appears to act directly and immediately on the nerve-tissue, as in cases of neuralgia resulting from atmospheric changes, particularly from electric states of the atmosphere. In other instances, the effect may be produced through the medium of the circulation, by malaria and blood-poisoning of different kinds. Anæmia, again, especially in females, is among the most common causes of neuralgia; as is also hysteria, even when unattended by anæmia. Disorders of digestion, constipation, the sudden suppression of secretions, or of habitual hemorrhages, such as hemorrhoids, the catamenia, etc., may all be productive of neuralgia in persons already predisposed.

The points of diagnosis between this form of neuralgia and that which arises from neuritis or inflammation of nerves, are very important, because the treatment required is very different in the two kinds of cases. In non-inflammatory neuralgia, although the pain may be excited or aggravated by the slightest touch, it is generally relieved by firm pressure, which is not the case in neuritis. Moreover, the pain is always interrupted by remissions of variable length in different cases, and is extremely varied in its character. It begins and ceases suddenly, and is apt to shift from one branch of a nerve to another, with a rapidity and intensity which are never experienced in neuritis. Antiphlogistic treatment, which relieves the latter, frequently aggravates non-inflammatory neuralgia.

NUTRITIVE AND OTHER CHANGES RESULTING FROM INJURIES AND DISEASES OF NERVES.

(1) *Changes due to Injuries of Nerves.*

In the earlier part of the present century a few observers occasionally and incidentally noticed the morbid effects of injuries of nerves on the nutrition of certain tissues; but it is only within the last ten or twelve years that the subject has been systematically studied. These lesions of nutrition consist chiefly of,—

(*a*) Diminution of temperature in the parts to which the injured nerve is distributed.

(*b*) Cutaneous eruptions, ulcerations, and alterations in the color and texture of the skin, and its appendages.

(*c*) Increase or diminution, and alterations in the quality, of its secretions.

(*d*) Periodical swelling of joints and other parts of a member.

(*e*) Atrophy and contractions of muscles supplied by the injured nerve, with distortion and stiffness of joints.

(*a*) The effect of injuries of nerves and of nerve-centres on the temperature of paralyzed parts was well investigated in the early part of this century by several English observers, particularly by Earle and Yelloly.

Earle excised a portion of the ulnar nerve of a girl for severe neuralgia, and five years after he found the temperature of the paralyzed parts decidedly diminished. He also found that they were unable to resist the injurious effects of cold. Frosty weather produced blistering and ulceration of the little finger.[1]—Yelloly mentions a case of anæsthesia, in which similar effects were produced by warmth.[2]

Mr. Jonathan Hutchinson, in a valuable and interesting article on "Injuries to Nerve-trunks,"[3] observes that the parts paralyzed by division of the nerve which supplied them, could never, even in the warmest temperature, be raised to that of adjacent, unparalyzed parts. "Nor does even the existence of active inflammation raise the part to the normal standard, although it much increases it." "It would appear, therefore, that while a paralyzed part can be cooled to almost any extent, it cannot be raised by artificial heat beyond a certain point, and that point much below the maximum of its uninjured counterpart."

(*b*) Romberg, more than thirty years ago, very clearly described some of the most important nutritive changes that the skin and its appendages undergo, when deprived of the proper supply of nerve-influence. There is found, he observes, an increased branny or scaly desquamation of the epidermis, accompanied by an absence of transpiration. The nails curve in, they become rough and ragged, and fall off.

He mentions a case of Dieffenbach's, in which there had been violent pain for ten years in the right foot. On the outer and posterior side of the thigh, near its middle, there was a tumor about five inches in circumference, which was also painful, and, when pressed, augmented the pain in the foot. The tumor was removed in 1836, and Romberg saw the patient two weeks after. There was complete anæsthesia in the parts supplied by the peroneus and tibialis nerves. The muscles of the leg and foot were paralyzed. Ulceration appeared early in the heel. Soon after, the nails exfoliated. At the end of three years, Romberg saw the patient again. She rested on the external edge of the right foot, which thus presented the appearance of varus. Further ulceration ensued, with necrosed bone, and desquamation of the epidermis, like psoriasis, the color of the skin being dark red and shining.[1]—Hamilton relates a case of Mr. Crampton's, in which puncture of the musculo-cutaneous nerve during the operation of bloodletting, was followed by the most severe neuralgia and other symptoms, and the wounded arm became *covered with hair.*[2]—Larrey mentions the case of a soldier who received a kick from a horse over the right eyebrow. The frontal sinus was fractured, and after some days, cutaneous hyperæsthesia and tetanic symptoms of the same side supervened. To Larrey's great surprise, the hair and moustaches of the injured side bristled up and became exquisitely tender to the slightest touch. About a year later the nails became ragged and rough, and fell off.[3]—Similar effects were observed by Bellengeri from a contused wound above the supra-orbital foramen. The hair on the injured side not only became stiffer, but grew with much greater rapidity.[4]—Pouteau records a remarkably interesting case, with symptoms similar to those of Larrey and Bellengeri, and resulting from a contused wound of the supra-orbital nerve.[5]—In a young lady, who came to me with protracted neuralgia of a circumscribed portion of the scalp, the hair over the painful part was not only coarser and stiffer, but perfectly white. Reading, or playing the piano for a few minutes only, brought on the most insupportable and indescribable feel-

ings, radiating as it were from the affected part.—In a case of temporal neuralgia mentioned by Trousseau, the hair on the affected side turned white, and acquired considerable stiffness in a very short time.

With regard to cutaneous eruptions resulting from injuries, numerous interesting observations, besides the one already quoted from Romberg, have been recorded by Rayer,[1] Earle[2], Rouget,[3] Oppolzer,[4] Charcot,[5] Raynaud,[6], Ruhl,[7], Thomas,[8], Paget,[9] Brodie,[10] and others. These cutaneous affections have been shown to consist chiefly of erythema, and of vesicular eruptions allied to eczema, erysipelas, and herpes. Mr. Paget has given an excellent description of the erythema observed in cases of injured nerves. "In well-marked cases," he says, "the fingers which are affected are usually tapering, smooth, hairless, almost void of wrinkles, glossy, pink or ruddy, or blotched as if with permanent chilblains. They are commonly also very painful, especially on motion, and pain often extends from them up the arm."

It is to Drs. Mitchell, Morehouse, and Keen, of the United States, that we owe the most precise account of the different morbid changes in the skin, and other tissues, resulting from particular injuries of nerves.[11] They have shown that the changes in the skin which follow wounds of nerve-trunks are of two kinds. The first is the result of *entire* division of the nerves of the part, with palsy of the whole limb. In most instances there is early œdema of the part. The skin thickens and dries; the epithelium hangs in patches here and there, and is yellow and even pale-brown. These peculiarities, however, are partly the consequence of mere disuse. But the nails become curved as in tubercular disease.

The second kind of pathological change is the result of only partial division of the nerve. The skin is deep red or mottled, or red and pale in patches. The cuticle seems partially lost, so that the cutis is exposed in places. The sub-cuticular tissues are nearly always shrunken. The surface of all the affected parts is glossy, generally devoid of wrinkles, and perfectly free from hair. Sometimes the fingers are dotted with islets of thin and red and glossy skin. This glossy appearance of the skin is always accompanied by pain, generally of a burning character.[1] "No particular time can be named as the period at which these changes in nutrition first show themselves. This alone can be said, that they do not belong to cases of complete destruction of the nerves. They may begin within a few days, or at any later date; but usually they arise while the wound is healing."

If the nerves of the hand be injured, the hair, after some months, disappears from the affected fingers, and the nails undergo remarkable alterations. These alterations consist of a curve in their long axes, an extreme lateral arching, and sometimes a thickening of the cutis beneath their extremities. In other instances the skin at that end of the nail next the third finger-joint becomes retracted, leaving the sensitive matrix partly exposed. At the same time the upper line of union of skin and nail retracts into or under the latter part, and in place of a smooth edge is seen through the nail as a ragged and notched border. "No deformity of the nails in tubercle at all approaches that which nerve-wounds occasion. Indeed, we think it would be possible for one familiar with these cases to diagnose the existence of nerve-lesion from the form of these protuberant and oddly-curved nails." When the nails of the toes have been attacked, the curving is as marked, but a distressing ulceration is apt to occur at their angles, and to break out again and again. The best remedy then is excision of the outer edge of the nail, matrix and all.[2]

In a case mentioned by Mr. Jonathan Hutchinson of division of the ulnar nerve, the nail of the little finger, about two months after the accident, came off, together with the skin, "like the end of a glove." It grew again, but not to more than half its original size.[3]

(*c*) *Alteration of secretions after injury of nerves.*—We have already seen that after the nerves of a limb have been completely divided, the skin is generally dry: but injuries of nerves without complete section modify the secretions in regard both to quality and quantity. The secretion is generally abundant, and sometimes intensely acid, so that an odor like vinegar can be smelt in the neighborhood of the patient. In one instance the odor of the

sweat was "disgustingly heavy," and resembled the smell from a bad drain.[1]

(*d*) *Periodical swelling of joints, etc.*—This peculiar affection, which is particularly interesting to the surgeon, is the result of both idiopathic neuritis and traumatic affections of nerves. It so closely resembles ordinary rheumatism or gout that it is not easy to point out the distinguishing characters of the two kinds of disease. Remak calls it *arthritis spuria.*[2] Dr. Mitchell has recorded some very interesting cases of this affection in the American Journal of the Medical Sciences (1869, vol. lviii.). It may occur at any time after the first few days of injury to a nerve, and may attack any articulation, or all the articulations of a member. Once fully established, it keeps the joints stiff and sore for weeks or months. When the acute stage is past, the tissues about the articulations become hard, and partial anchylosis results. Of all the agencies which impede movement, it is the most difficult to relieve.

(*e*) *Atrophy and contraction of muscles from injury of nerves* has been for many years carefully investigated by Dr. Duchenne (de Boulogne), whose work (Électrisation localisée) contains a number of the most valuable cases. Complete division of a nerve is always followed to a certain extent, in the course of time, by atrophy of all the muscles to which that nerve is distributed; and the wasting is much more rapid when the main artery has been divided or interrupted. But in *partial* division or injury of the nerve, only those muscles are liable to suffer which are supplied by the injured fibres, and in this case the wasting is more rapid and decided than when the nerve has been *completely* divided. Thus, a whole group of muscles may be affected, or only part of a group; a single muscle only, or even only part of a muscle, which, moreover, may be affected in either a lateral or a longitudinal direction. So soon as the muscular fibres begin to suffer in nutrition, their tension or tonicity diminishes, they become softer, more flabby, or relaxed. Sooner or later they begin to waste, and after a time, in many instances, they acquire a kind of morbid tension, and contract or shorten permanently to a greater or less extent, causing a variety of deformities, alterations in the form of the joints, and loss of natural movement. This morbid tension, however, is not always in proportion to the degree of atrophy, for in some instances the wasting is slight while the muscular contraction is extreme. Moreover, a muscle may become shortened from paralysis of its opponent, and this condition must be distinguished from the shortening which is due to atrophy.

Early loss of tone in a muscle, from injury of its nerves, is a bad sign. Rapid diminution, of size and contraction, when due to nutritive changes, is still worse. All these changes are ominous of ultimate deformities and permanent loss of power.[1] In the diagnosis and prognosis, no less than in the treatment of injuries to nerves and their consequences, electricity plays a most important part; and for its first application to these purposes, we are chiefly indebted to the remarkable sagacity and skill of Dr. Duchenne (de Boulogne).[2] The way in which he has made it an instrument of diagnosis and prognosis, in diseases and injuries of nerves, is no less important than beautiful in a practical point of view.

[Important advances have been made in electrical diagnosis and therapeutics, since the appearance of Duchenne's Électrisation localisée. The changes, qualitative and quantitative, in the electrical condition of nerves and muscles, have been designated by Erb, "the reactions of degeneration." It is necessary to distinguish between nerve- and muscle-reactions, yet the same electrical energy applied directly to the muscle, or to the motor nerve innervating it, causes contractions. Hence, it follows, we have in the muscular movements also a means of ascertaining the condition of the motor nerve.

When a motor nerve is injured and inflamed, without being completely divided or destroyed, there is a brief period during which the electro-contractility of the muscles innervated by it, is heightened; that is, to a less stimulation than in health, the muscles readily contract.

---

[1] Mitchell, Morehouse, and Keen, op. cit., p. 86.

[2] Allg. med. cent. Zeitung, Berlin, 1863. Ueber den Einfluss des Nervensystems auf Krankheiten der Knochen und der Gelenken.

[1] Mitchell, Morehouse, and Keen, supra, p. 120.

[2] The following statement is made by the most competent judges on this subject. "As respects its value in traumatic lesions of nerves, we feel constrained to state that it has been understood and rightly appreciated by Dr. Duchenne alone. After a year of great experience in the use of electricity, we are still satisfied of the essential correctness of almost every proposition on the subject which this distinguished physician had laid down." (Mitchell, Morehouse, and Keen, op. cit., p. 136.) I am glad to learn from Dr. Duchenne, that a somewhat abridged English translation of his laborious work is in course of preparation. It ought to be in the hands of every surgeon and physician. No one, judging from its unhappy title alone, would expect to find in it so rich a mine of pathological facts.

This heightened electro-contractility corresponds to a period of excitation of the nerve elements, coincident in point of time with the stage of congestion of the inflammatory process. If the inflammation continues and is destructive, softening and disintegration of the nerve-elements occur, and from the second or third day a quantitative decline in the electric excitability of the inflamed nerve takes place. If the injury done is irreparable, or if the inflammation destroys the nerve-elements, this quantitative decline continues, so that by the twelfth day, sometimes earlier, the electric excitability entirely disappears. This change in the electrical reactions of the diseased nerve, begins at the point of injury and spreads thence to the periphery. If the injury or inflammation is less severe and destructive, and the nerve-elements remain in part unimpaired, the electric excitability will not be entirely extinguished, and with the final restoration of the nerve-elements, will return the normal electrical reactions. In the course of recovery of the nerve, the power of response to the will is restored before the galvanic or faradic excitability is recovered. In other words, the muscles react to voluntary impulses, under these circumstances, when the strongest galvanic and faradic currents will not excite a tremor.

The muscular reactions are different. In the case of inflammation or injury of the motor nerves, the muscles exhibit the reactions of degeneration. In the mildest cases, there may be merely a quantitative decline in the faradic reactions, but in a typical case, in a few days (by the end of the first week) a decline, and then loss of the excitability to the faradic current takes place, but at the same time the response to the galvanic current becomes abnormally ready, and a less strength of current than suffices to move the muscles in health will produce strong contractions. If the destructive changes proceed, and the muscles degenerate so that their contractile elements are entirely destroyed, then a stage is finally reached when any strength of the galvanic current will produce no movements. The reactions to the electric current thus become exceedingly important in determining the condition of the nerve and muscles. If the injury only suffices to cause a quantitative decline in the response of the muscles to the faradic current, the injury or disease is by no means so important as in those cases in which even the strongest faradic current causes no movement, but a great readiness of contraction on the application of a weak galvanic current has developed. The case is still more serious, when no strength of galvanic current will cause a response on the part of the muscles.

The statement in the original text that the differentiation between cerebral and spinal paralysis was, in part, made by the loss of faradic excitability in the latter, and its preservation in the former, is true to a limited extent only, and requires some further explanation. In hemiplegia, which we may take for illustration of a cerebral paralysis, the faradic excitability may be heightened, may be merely normal, or may be reduced. The decline in the excitability, chiefly quantitative, is due to secondary changes in the muscles. In spinal paralysis the faradic excitability may be present, may be lessened quantitatively, and qualitatively, or may be entirely wanting. The faradic excitability is normal in those cases in which the spinal cord is healthy at that point from which the nerves come off to the paralyzed parts, and is lost in the opposite condition. For example, in a case of transverse myelitis, with paraplegia, occurring in a part of the cord entirely above the dorso-lumbar enlargement, from which the nerves are given off to the inferior extremities, the faradic excitability will be normal; but if the dorso-lumbar enlargement is diseased in its entirety, or in the motor columns, there will ensue loss of the faradic excitability, and the phenomena of the reaction of degeneration will develop. In the "myopathies of spinal origin"—infantile paralysis, progressive muscular atrophy, etc.,—the same symptoms appear: with paralysis occur loss of faradic excitability, and an abnormal readiness of response to the galvanic current. In these, as in the preceding examples, the loss of faradic excitability occurs in the muscular groups, innervated by nerves coming from a diseased portion of the cord. There are maladies of the spinal cord, however, which seem paradoxical in respect to the electrical reactions. For example, in disseminated sclerosis, some muscular groups of one extremity will have lost, and other muscular groups will have retained their excitability to the faradic current. Such a state illustrates, if rightly interpreted, the law above expressed: those muscles receiving their innervation from a healthy portion of the cord preserve the normal reactions, and those communicating with a diseased tract, present the reactions of disease.

Certain terms and formulæ are now used to express the changes in the reactions of nerves and muscles. The normal reactions are taken as the standard. The nerves, as we have seen, are affected equally by the galvanic and faradic currents, but different formulæ are required to express the behavior of muscles when stimulated by either current. In the normal, the weakest galvanic current producing a muscular contraction, is the cathodal closing (C C). With a strong current, there are decided anodal opening and closing contractions (A O C and A C C), and with the cathodal closing, tetanic contractions (C C C). When the reactions of degeneration occur, it should be borne in mind, as has been stated, that there occurs a progressive decline in the power of the paralyzed muscles to respond to the faradic current. This decline in the *faradic* irritability takes place near the end of the first week, and during the second week ends in complete loss. The galvanic irritability exhibits characteristic alterations. During the first week of the paralysis, the power of response of the muscles to the galvanic current declines with the faradic, but in the course of the second week, a very great increase of the excitability of the muscles to the galvanic current is developed. This augmented excitability increases subsequently, and is accompanied by qualitative changes in the order and manner of muscular contraction. As has been before stated, so excitable have become the muscles to the galvanic current, that a strength of current inadequate to cause muscular contractions in health, now induces active movements, but the contractions, instead of being almost instantaneous, are slow and prolonged. With the increase in excitability, there ensues also a qualitative change in the law of muscular contraction above expressed. This change consists in a decided increase in the anodal closing contraction, so that it soon equals, even surpasses, the cathodal. At the same time the cathodal opening contraction increases more than the anodal opening contraction, and soon equals, then exceeds it. After six or eight weeks, or longer, a gradual diminution in the galvanic excitability takes place, but the inversion of the normal formula just described, persists. Gradually, stronger and stronger currents are required to produce contractions, and if the muscular atrophy persists, when the contractile elements finally disappear, no strength of current will produce any response. Persisting in the abnormal law of contraction, the last indication of the presence of any contractile elements is the occurrence of an extremely feeble anodal closing contraction. When the spinal injury or disease is remediable, the excess in the galvanic excitability of the muscles lessens, and presently the muscles react again to the faradic current. Duchenne has made the important observation, that in some cases, notwithstanding the failure of the muscles to respond to the faradic current, persistent applications have at length caused contractions.

In the treatment of the spinal paralyses, the galvanic current must be employed to exercise the paralyzed muscles, until the power of response to the faradic current is restored, when it may be used to complete the cure. If neither current will induce contractions, the case may be regarded as hopeless, for this absence of response indicates the final disappearance of the muscular elements. The faintest response to galvanism gives rise to hope, since a persevering exercise of the undestroyed filaments will sometimes accomplish great results in very unpromising cases.]

When a healthy muscle is made to contract by means of electricity, it becomes the seat of a peculiar pain, which is called electro-muscular *sensibility*. This pain, however, is not caused by the contraction, for it is still experienced in muscles which have lost the power of contracting under the influence of electricity. The property of contracting under the same influence, is called electro-muscular *contractility*. Now it has been laid down by Dr. Duchenne as a law which is very remarkable, but which subsequent experience has fully confirmed, that the persistence of this property of electro-muscular contractility is not necessary for the exercise of *voluntary* contraction.[1] On the other hand, muscles that are partially or completely paralyzed, with regard to the *will*, may sometimes retain their normal degree of electro-muscular contractility; while in certain cases, muscles which have lost, to a very unequal degree, the power of contracting under the stimulus of electricity, may seem to be all equally paralyzed as regards the *will*. There is another remarkable and important practical point to be remembered, viz., that although the retention of electro-muscular contractility is not necessary for the exercise of voluntary contraction, yet that whenever it is lost, or even impaired, the prognosis is unfavorable in reference to the return of *voluntary* control, and indicates that the affected muscles will suffer in their nutrition and become atrophied. It is curious, however, and very important, that notwithstanding the loss of electro-muscular contractility, the *therapeutical* power of faradization may still exercise its influence on the paralyzed muscles. If electro-muscular sensibility be retained, the chances of recovery are more favorable; and whenever it is impaired, if pain be excited by the action of electricity, the effect is a favorable sign.

Different forms of paralysis which depend on traumatic affections of nerves, and which may appear to be exactly alike—which cannot, indeed, be distinguished from each other by the ordinary modes of diagnosis — may nevertheless differ essentially from each other with regard to their progress, their gravity, or their termination. The electro-muscular test alone enables us to discriminate those cases in which muscles will remain paralyzed and become atrophied in the course of a few months, from other cases in which it may be predicted with certainty that the paralysis, without atrophy of the muscles, will disappear, either spontaneously or by means of faradization.

---

[1] De l'Électrisation localisée, 2^{me} éd., p. 330.

A man, under the care of the late eminent surgeon M. Roux, at the Hôtel Dieu, had dislocation of the humerus forward. The reduction was deferred till the next morning, when it was found that the head of the bone had changed its place to the axilla. The muscles of the arm, forearm, and hand were completely paralyzed to the will, but sensibility was retained. This state of things having continued for nearly a month, with gradual wasting of the muscles, Dr. Duchenne was requested by M. Roux to examine the arm by means of faradization. All the movements of the upper extremity were found to be completely abolished, and it would therefore have been natural to conclude that all its muscles were equally affected, or rather that all the nerve-fibres that supplied them were equally injured. But it was found that some of the muscles had completely lost their electro-muscular contractility, and subsequently wasted rapidly; while the other paralyzed muscles, which had not suffered in this way, not only escaped atrophy, but recovered their voluntary power after a few applications of electricity. The deltoid had partially lost its electro-muscular power, and therefore required for its restoration a little longer time than those which wholly retained it.

In paralysis resulting from *cerebral* disease, the electro-muscular contractility remains unaffected, and therefore faradization is of great importance in the differential diagnosis of paralysis which follows injuries of nerves or affections of the spinal cord.

A man was admitted into the Hôpital de la Clinique, for paralysis of the right arm. According to his own account, some days before his admission he woke in the morning with his arm paralyzed, but perfectly free from pain. At first he only felt formication in the fingers, with a sensation of numbness and coldness in the whole limb; but a few days after, he began to experience a lancinating and intermitting pain of no great intensity in the right cervical region. The suddenness of the attack, without any preceding pain, occurring in a young man who had not suffered from any traumatic lesion of nerves, or been apparently exposed to any other influence that might occasion paralysis of the arm, would reasonably suggest a cerebral cause. But on examining the limb by means of faradization, it was found that the majority of the muscles had lost, in a greater or less degree, their property of contracting under the stimulus of electricity—a property which, as already stated, is retained in paralysis resulting from cerebral causes. Judging from these facts, Dr. Duchenne at once came to the conclusion, that the real cause of the paralysis was to be referred to some alteration either of the brachial and cervical plexus or of that portion of the spinal cord from which they derive their origin. On further examination a month after by M. Nélaton, who then for the first time took charge of the patient, he was found to be affected with tertiary symptoms of syphilis. That distinguished surgeon thought that some kind of exostosis might be the cause of the paralysis, and accordingly prescribed the proto-iodide of mercury. After some days the pain ceased, and then the paralysis gradually disappeared from the muscles which had not lost their electro-muscular contractility.

Treatment.—For restoring the paralyzed and wasted muscles to their original condition, electricity is unquestionably the most important agent. It should be employed daily for at least ten or fifteen minutes, and each muscle should be separately faradized. The period when the treatment by electricity should commence must vary according to the peculiarities of the case. If the electro-muscular contractility remain intact, faradization should be employed as soon as possible. But when this property is lost —that is, when the nerve influence is no longer supplied to the muscles, and more particularly when the muscular sensibility is impaired—the treatment by electricity is of no service, and should not be employed until some months after the injury, or until there is good reason to believe that the nerve-lesion is repaired. In addition to electricity, friction and shampooing should be employed, with passive motion, and voluntary exercise of the muscles, as soon as voluntary control is in any degree restored. The douche is often of great service, particularly if hot and cold water be alternately used. Care should be taken to preserve warmth in the affected part. When flexion or extension of a limb occurs in consequence of contracted muscles, splints, bandages, and other apparatus will be necessary.

When the effects of the nerve-lesion are aggravated or prolonged by some peculiar diathesis, or when the health of the patient is suffering from severe pain and want of sleep, general as well as local treatment must be adopted. Narcotics, iron, and quinine, cod-liver oil, and phosphorus are the most worthy of recommendation. The hypodermic method is the best mode of administering narcotics. If morphia be employed, the first injection should not exceed the sixth of a grain.

(2.) *Changes due to Idiopathic Affections of Nerves.*

Although traumatic lesions of nerves give rise to the most serious nutritive changes in the tissues to which those nerves are distributed, it is not uncommon to find that idiopathic affections of nerves are followed by changes of a similar nature.

The principal alterations in the nutrition of the skin resulting from idiopathic neuritis and neuralgia are manifested in the form of herpetic eruptions. Rayer, I believe, was the first to point to neuralgia as the cause of these eruptions, while other writers, including even Valleix and Cazenave, regarded the neuralgia as a consequence of the cutaneous affection. Rayer's opinion, however, has been fully confirmed by subsequent observation. The pain is frequently found to precede the eruption, while the latter is sometimes seen to follow the course of the affected nerve.

Barensprung has recorded a very valuable case, to which I have already alluded, and which proves in the most convincing manner, the close relation between idiopathic inflammation of nerves and herpes zoster. The patient was a child one year old. The eruption extended round one side of the thorax from the sixth to the ninth rib, and after death, which resulted from tubercular disease, the roots of the sixth, seventh, and eighth intercostal nerves, but especially the seventh, were increased in size and of a red color, in consequence of the presence of enlarged and tortuous vessels in the neurilemma. The diameter of the seventh intercostal exceeded by more than one-half that of the fifth or the ninth. The corresponding intervertebral ganglia were firmly adherent to the intervertebral canal; their connective tissue presented an inflammatory redness, and they were decidedly increased in size.[1]

MM. Charcot and Cotard have related the equally interesting case of a woman, aged seventy-eight, from whom a cancer of the right breast was removed in August, 1865. In October of the same year, she complained of sharp pains in the right shoulder, and in the right half of the neck. These pains were continuous, but increased in their severity at intervals, during which the patient appeared to suffer the most acute pain. About December 15 of the same year, an herpetic eruption made its appearance over the whole right half of the neck, limited exactly, both before and behind, to the median line. The eruption occupied all the other parts of the skin which are supplied by branches of the cervical plexus on the right side, but was not followed by any diminution of pain. The patient died on December 26, after symptoms of effusion into the pleura on both sides. On post-mortem examination it was found that while both the anterior and posterior roots of the spinal nerves in the cervical region were perfectly healthy, the intervertebral ganglia, as well as the compound tracks formed by the union of the two roots, presented a slight tumefaction, and a vascularity which was manifested by a bright red color. The difference was striking when the corresponding parts on both sides were examined.[1]

Among the most remarkable cases of neuritis giving rise to herpetic eruptions of the skin, are those which M. Leudet, of the Hôtel-Dieu of Rouen, has shown to be caused by the inhalation of carbonic acid.

When the symptoms of asphyxia have subsided, it is not uncommon, after a variable number of days, to find certain disorders both of sensibility and motion. The lower extremities are the parts which are usually affected, although different parts of the nervous system are sometimes involved. In one case which proved fatal, M. Leudet found the right sciatic nerve at least one-third thicker than the left; its neurilemma was injected, thicker, and more indurated than that on the opposite side.

In these singular cases, the skin was affected by eruptions similar to herpes. These eruptions appeared almost immediately after the subsidence of the symptoms of asphyxia, and in general, lasted only a short time.[2]

Herpes is not the only cutaneous eruption that has been found to follow neuralgia and neuritis, whether traumatic or idiopathic: lichen has been observed by Canuet in cases of neuralgia;[3] acne and erysipelas have been seen by Hasse[4] and Romberg[5] to accompany the same affection.

[1] Mémoires de la Société de Biologie, 1866, p. 41. From such observations as these, Barensprung seems to be quite satisfied that the intervertebral ganglia on the posterior spinal roots, give origin to the so-called trophic nerves; but it appears to me that facts do not warrant the conclusions at which he arrives.

DISEASES AND INJURIES OF NERVES.

PART II.

REMOTER CONSEQUENCES OF NERVE-LESIONS.

By C. E. Brown-Séquard, M.D.

Revised by Roberts Bartholow, M.D., LL.D.

Introduction.

Two distinct groups or classes of symptoms may be caused by a lesion of a nerve; in one class the symptoms are the effects of the *loss of function* or *cessation of action* of the nerve; in the other, on the contrary, they are produced by *an action* of the injured or irritated nerve. In the first class, therefore, the symptoms depend on *lack of action*, while in the second, they are due just to the reverse, *i. e.*, *existence of action*, in a nerve.

Each of these two classes of symptoms may be subdivided. As there are at least four different kinds of nerves, four distinct kinds of symptoms of loss of function or cessation of action may be observed after a lesion of a nerve:—

1st. There may be paralysis of motion.

2d. There may be paralysis of centripetal nerves (sensitive, incito-motory, etc.).

3d. There may be paralysis of the vasomotor nerve-fibres, in consequence of which the bloodvessels may be distended and full of blood.

4th. There may be paralysis of the special nerve-fibres, the normal influence of which consists in giving activity to nutrition and secretion.

Leaving aside these four kinds of symptoms, I will confine myself here to the study of some of the effects of irritation of nerves. These effects may be grouped under two heads,—the *peripheric*, or *direct*; and the *remote*, *indirect*, or *reflex*. Of the peripheric, or direct effects, I will simply say that they give origin to five kinds of symptoms:—

1st. Contraction of muscles.

2d. Referred or subjective sensations (formication, pricking, feelings of pain, heat, cold, etc.).

3d. Diminution in the quantity of blood, owing to the contraction of bloodvessels in the part where the injured nerve distributes its fibres.

4th. An increase in the quantity of blood when the irritated nerve-fibres are those having normally the power of increasing the interchange between the blood and the tissues.

5th. In consequence of one or the other, or of a combination of the just-mentioned kinds of changes in the circulation of blood, there are various alterations of nutrition or secretion in the eyes, the skin, the joints, etc.

Of these five kinds of effects of irritation of nerves, four, viz., the first, third, fourth, and fifth, may also be caused either by a genuine reflex action, or by some peculiar influence upon or through the nervous centres. I propose here to treat only of these four last kinds of symptoms.

All the functional affections or disorders, and most of the organic diseases, are frequently produced by an influence exerted upon the nervous centres by an irritation of any part of the length of a nerve. This irritation may occur in the ramifications of a nerve in a mucous membrane or the skin (and be due to worms, a calculus, etc., or to cold); or it may depend on an organic or a functional affection of the trunk of a nerve (as in cases of wounds, burns, tumors, or neuralgia). In most instances an inflammation of the various viscera owes its origin to a reflex influence on the organ which becomes inflamed, proceeding from the irritation of some cutaneous nerve-fibres by a draught of cold air. I will not say more here on this reflex origin of visceral inflammation caused by cold acting on the skin, my object being only to give an outline of the various effects of injuries or diseases of all parts of nerves excepting the network of their terminal ramifications.

Of the various reflex and other remote effects of irritation of centripetal nerves, the following are the principal, of which I propose to speak successively; *epilepsy*, *tetanus*, *hysteria*, *catalepsy*, *chorea* and other *convulsive affections*, *trembling palsy*, *paralysis* of various kinds (*local paralysis*, *hemi-*

plegia, etc.), *anæsthesia*, *amaurosis*, *deafness*, *collapse*, *insanity*, *delirium*, *aphasia*, *coma*, *neuralgia* and other *painful affections*, *inflammation*, *atrophy*, *hypertrophy*, and other *morbid alterations of nutrition and secretion*. After having mentioned clear and positive facts, showing that all these affections may be caused by an injury to, or a disease of, a nerve, I will briefly give the rules concerning the diagnosis and treatment of these effects of injuries and diseases of nerves. This essay will therefore consist of two sections: the first, relating to facts demonstrating the existence of a great variety of reflex and other remote effects of irritation of centripetal nerves; the second, giving the principal features and rules of diagnosis and treatment of these effects of diseases and injuries of branches and trunks of nerves.

Section I.—Affections of the Nervous Centres and other Organs, Caused by an Injury to, or a Disease of, a Nerve.

Epilepsy.—Of all the nervous and other complaints that may be due to an irritation starting from the trunk, branches, or ultimate ramifications of nerves, very few, if any, are more frequent than epilepsy. Diseases of all the mucous membranes, or their irritation by worms, diseases of the cerebral or spinal meninges, dentition, etc., are known to be frequent causes of this convulsive affection. But it is not so well known, that an injury to, or a disease of, a nerve, not rarely produces epilepsy. Indeed, even a man of great authority as regards epilepsy, Dr. Herpin,[1] has lately maintained that in cases in which this affection seemed to have been caused by an external injury, it was, in reality, due to a disease of the nervous centres. It is most important that medical practitioners should not be misled by such an opinion. The rational treatment of that form of epilepsy which appears after a wound, or an organic affection, of a nerve, would certainly be neglected if such a view were admitted. It is, therefore, necessary to demonstrate that in a number of cases an epileptiform affection and also the most genuine epilepsy have been caused by a lesion of a nerve. This demonstration is given by the following kinds of proof:—

1st. In a great many cases, epilepsy has appeared in persons in whom there was no other cause for its production but a wound, a burn, a tumor, an inflammation, or a neuralgia.

2d. In a number of the above cases a peculiar sensation, generally miscalled aura epileptica, arose from the seat of the irritated nerve before all or most fits.

3d. In many of the same cases, the application of a ligature round a limb above the seat of the irritation often prevented the occurrence of fits.

4th. In some of the same cases a pressure on the seat of the external irritation invariably brought on a fit.

5th. In many cases of epilepsy apparently due to an irritation of a nerve, the section of that nerve above the seat of irritation, or the amputation of the limb; the extirpation of a tumor, of a cicatrix, of a decayed tooth, of a carious bone, etc., have cured the patient.

6th. I have discovered, in certain animals, that the irritation of the sciatic nerve by a broken bone, or by some other causes (crushing, tying, or cutting), invariably produces a temporary or persistent epilepsy. This convulsive affection never disappears without treatment, unless the irritation has ceased in the sciatic nerve.

These various facts clearly prove that epilepsy may be due to an irritation of a nerve, and exist without any serious organic change in the nervous centres. For the details of cases like those I have mentioned I will refer the reader to the new edition of my work on epilepsy, which will soon be published. I will only say here, that some of these cases have been observed by perfectly reliable men, such as Sir Astley Cooper, Sir Benjamin Brodie, Dieffenbach, Baron Larrey, etc. I will give one of those cases as a good specimen of reflected epilepsy. It was put on record by Dr. W. Laing, of Aberdeen.

M. D., aged twenty-one, had the left hand lacerated by machinery. She went on well till the night of March 6, when she was seized with convulsions, and, after a day or two, with trismus and other tetanic symptoms. On April 7 she was dismissed *cured;* but on June 24 she returned to the hospital. About a fortnight before her readmission she suddenly fell down in an epileptic fit; and since, the attacks have become more and more frequent, recurring five or six times a day, and lasting about five minutes, after which she remained a considerable time in a state of stupor. On the 25th the fits were so severe that she was put in the strait-waistcoat. When the fits were slight, they were confined chiefly to the injured arm. On touching the fingers smartly, the arm was convulsively withdrawn; and, when this was done while she was lying in a state of stupor, violent convulsions of the arm were produced. The patient often felt a sensation arising from the injured hand previous to her fits. As the remainder of the hand was of little use, the forearm was amputated; the patient never had the slightest appearance of epilepsy after the operation, and was dismissed cured, a month afterwards. The digital branches of the median nerve and a branch of the ulnar were found enlarged to four or five times their usual size, and their extremities bulbous, and firmly imbedded in a hard cicatrix.[1]

---

[1] Des accès incomplets d'épilepsie, par Th. Herpin, p. 36. Paris, 1867.

Tetanus.—Referring to the article on TETANUS in the first volume of this work, I will only say a few words on the important questions relating to the nature and to the local treatment of this affection.

I am really surprised that some persons still doubt that it is owing to a peculiar influence, exerted on the circulation of the blood and the nutrition of the spinal cord and the medulla oblongata, by the irritation of a centripetal nerve, that tetanus arises from a traumatic lesion. I hope that the following facts and reasoning will show that this convulsive affection is truly dependent upon an irritation arising from the injured nerves, and not—as Dr. B. W. Richardson, Roser, Billroth, and others are inclined to admit—from toxæmia.

The relation between the wound and tetanus seems to be positively established—at least, in those cases in which the muscles attacked with spasms are on the side injured. Lepelletier, Sir Gilbert Blane, Swan, Dupuytren, and Mr. Curling,[2] who cites the preceding authors, have seen such cases. My friend, Dr. G. H. B. Macleod,[3] relates two cases of fatal tetanus, in which the tetanic spasms were almost entirely limited to the side injured. Baron Larrey states that when the wound causing tetanus is in the anterior part of the trunk, emprosthotonos is the form generally observed.

Other strong arguments in favor of the view that traumatic tetanus is caused by a peripheric irritation, are: 1st, that very frequently the muscles in the neighborhood of the wound are either the first attacked or the most affected with spasms; 2d, that in many cases it has been observed by myself and others, that even a slight pressure on the wound or the cicatrix has increased the spasms or produced them, in periods of relaxation (after chloroformic anæsthesia, for instance).

It may seem strange that tetanus will sometimes follow even the slightest wound, and that it will come at any period of inflammation or cicatrization, and even when there is no pain at all in the wound or its neighborhood. But this last fact is no objection to the view that tetanus takes place in consequence of an irritation starting from these parts, as we know that all the morbid or normal influences on circulation and nutrition in the nervous centres, may proceed from the periphery, without any pain, or even without the least perceived sensation.

The kind of lesion which most frequently produces tetanus, implies that there is a great irritation of nerves, although there may be no marked pain. In a table given by Mr. Poland in this work (Vol. I., p. 566), we find that out of 1364 cases of major and minor operations at Guy's Hospital, there is but one case of tetanus; while out of 398 cases of compound fractures and 594 cases of wounds of all varieties, there were 18 cases of tetanus; giving a proportion, when the nerves were simply divided, by a sharp knife, of one case of tetanus out of 1364 patients; and of one case out of 55 patients, after wounds and fractures, when the nerves were bruised or much irritated. In a statistical table given by Dr. Friederich,[1] the influence of great irritation of nerves in causing tetanus is also demonstrated: out of 176 cases of that affection, only 11 occurred after amputation, and 33 after gunshot wounds, while 61 were due to contusion or comminutive fracture, and 71 to wounds by puncturing instruments, or dilaceration and bruising of tissues by nails, pieces of wood, etc. Dr. Lawrie's statistics agree with those of Friederich.[2]

The cases of cure of tetanus either by an amputation of a limb or by section of a nerve, clearly prove the dependence of this affection on an irritation starting from some peripheral part of a nerve. The same conclusion flows out from numerous facts like the following, to which I might add many others. Tetanus is pointed out to have been caused by a small splinter of bone sticking in the radical nerve (Hennen), by a portion of a whip embedded in the cubital nerve (Dupuytren), by an application of caustic potash on the coraco-brachial nerve (Frere), by shot corns in the tibial nerve (J. Hutchinson), by a splinter of wood in the radial nerve (Morgan), by neuritis (Curling, Lepelletier, Froriep, and others), by ligatures on nerves of limbs (Larrey, Béclard, Portal, etc.), by a small piece of broken bone passing through the peroneal nerve (Wutzer and O. Weber), by the crushing of the anterior tibial nerve between fragments of broken bone (Alquié), and by partial division or tearing of nerves (Swan, Liston, Billroth, etc.). In cases in which the spinal cord was either inflamed or rendered extremely excitable, the section of a nerve or an amputation has been of no avail; and in some cases, also, in which an inflammation has been propagated high up in the trunk of a nerve, towards its roots, these operations have been useless; but such failures might have been avoided had these modes of treatment been applied earlier, and had all the nerves been divided higher up than they have been. I need not say that the simple division of a nerve should always be preferred to an amputation, unless there are some special reasons for this last operation.

Hysteria.—The extreme frequency of this affection in women renders it difficult to prove that it may be due to an irritation of a nerve. However, there are cases in which it seems quite clear that hysteria was really caused by a wound, or the irritation of a tumor.[1]

Two very interesting cases are reported by Dr. Parsons;[2] one observed by himself, the other by Dr. S. P. Hildreth.

Morgagni mentions the case of a young girl who, after a wound to a finger by the biting of a sparrow, was attacked with fits of trembling and screaming, recurring sixteen or eighteen times a day.[3]

Raynaud relates the case of a woman who, after having received a blow on the breast, had a first attack of hysteria. Two small tumors soon appeared at the injured place, and for seven years hysterical attacks occurred several times every day. These tumors were removed by Boyer, and immediately after the operation the attacks ceased, and did not recur again.[4]

Three years ago, in a patient of mine of a highly nervous temperament, but who never had had any marked symptoms of hysteria, convulsions and delirium, with some degree of lock-jaw, frequently appeared and ceased, during three or four days, after a slight wound by a needle in front of the knee-joint, just below the patella. The needle broke at the time of the accident, and a small part of it remained under the skin. As soon as the pain ceased in the little wound, after the extraction of the point of the needle, the patient got well, and has had no return of hysterical symptoms since.

Brachet has seen a temporal neuralgia produce hysterical fits every time it appeared, and for all the time it lasted.[1]

Sir Benjamin Brodie mentions several cases in which a wound was the cause of hysteria.[2]

A very curious case of hysteria in a man, cured by the removal of a tumor of the external ear, has been published by Dr. Bastien, in his inaugural dissertation.[3]

In hysteria as in epilepsy, an aura starting from some point of the periphery of the body may precede an attack, and also the aura may be created by a pressure on some part. In those cases the same means of treatment as in epilepsy may prove useful. These facts, and the cases I have briefly mentioned, show that hysteria, like epilepsy and tetanus, may be caused by an irritation of a nerve. I must say, however, that a persistent cure of hysteria is very rarely obtained. Various operations, such as extirpation of cicatrices, amputations, etc., to cure hysterical spasms due to an irritation of nerves, have proved beneficial only for a time, in several cases of Sir Benjamin Brodie,[4] of Mr. Hancock, Tyrrel, and Bransby Cooper.[5]

Catalepsy.—I have seen a case of this affection in which attacks were brought on at once by even a slight pressure on tender spots between the shoulders. Catalepsy, therefore may, like other neuroses, be produced by a peripheric irritation.[6]

Chorea.—St. Vitus's dance may be caused by an injury to a nerve.

In a case of Dr. Borelli, of Turin, chorea was caused by a neuroma of the foot, in a child thirteen years old. This convulsive affection was at once lessened, and in four days cured, after the extirpation of the neuroma.[7] Andral mentions a case of chorea caused by the irritation of a finger by a retroverted nail.[8] Dr. J. Malden has cured a woman of choreic movements by the extraction of a decayed tooth.[9]

Hydrophobia.—I will try to show elsewhere that the symptoms of this terrible affection depend on a local effect of the virus on the wounded nerves, and that some chance of cure might be obtained by division of the irritated nerves. Already in the last century, G. Hicks proposed this means of treatment against hydrophobia.[1] I owe to Dr. Stokes, of Dublin, the mention of a most important case, showing that there is good ground to hope that hydrophobia might sometimes be cured by amputation or division of a nerve.[2]

---

[1] An interesting case, published by Hamilton (Dublin Journal, 1838, vol. xiii., p. 42), shows how careful we must be as regards the signification of symptoms in hysterical patients. All the most characteristic features of neuritis existed in a patient after a wound, but they disappeared *at once* after a violent fit of hysteria.

[8] Cours de Pathologie interne, vol. iii., p. 304.

[9] Archives de Médecine, mars, 1855, p. 338; from Trans. Provincial Associat., vol. xix.

Tremulous movements.—The so-called *trembling palsy*, which so often consists simply in involuntary tremulous movements, without any palsy, may be caused by an irritation starting from a nerve.

Sabatier[3] relates the case of a young man, who, after a wound of the saphenous nerve, near the knee, was attacked with violent trembling of the leg and thigh, which lasted many months. In a patient sent to me by Mr. Erichsen, an injury to a nerve of the left arm has produced trembling in both arms. In another patient, for whom I was consulted by Mr. M. H. Collis, of Dublin, shaking palsy began in a fractured limb and thence extended to the other limbs. Several cases are on record showing that the shaking due to an external injury may become general.[4]

Rotatory convulsions.—I have found that an injury to the auditory nerve in animals is at once followed by rotatory movements. I do not know of any case of wound of that nerve in man having produced the same symptoms; but several cases are on record in which these movements have been observed in man when the auditory nerve was irritated by an inflammation or some other cause (an injection of caustic, etc.).

I would refer for these cases to my work on the Central Nervous System, p. 195, only adding here that since that publication I have seen three cases of that peculiar kind of involuntary movements, caused by an affection of the internal ear. An irritation of other nerves may produce the same effect. Dr. Krieg relates the case of a patient wounded on the forehead, and on whom a touch of the injured skin produced attacks of exceedingly rapid rotatory movements.[5]

Local convulsions.—It is well known that wounds of the branches of the fifth pair of nerves may by a reflex influence produce spasms of the muscles of the eyes, or trismus, or histrionic convulsions. It is known also that muscles of the limbs and trunk may be seized with either tonic or clonic reflected convulsions from an irritation of a nerve. Sneezing, hiccough, cough, and vomiting are sometimes also caused by the reflex influence of wounds. Spasms of the sphincters (*vesicæ et ani*), of the œsophagus, of the larynx, etc., are also among the reflected phenomena not rarely caused by an irritation of superficial nerves.

Contracture of bloodvessels.—Many experiments establish that bloodvessels will contract by a reflex action.[1] In hysteria and other nervous affections a reflex vascular contracture frequently occurs.

An eminent American clergyman has given me the details of a most remarkable case of prolonged reflex contracture of bloodvessels, he himself being the patient. After having violently struck his leg (two inches above the knee) against a piece of paling-fence, he was soon apparently cured of the local injury; but an influence upon the bloodvessels of the limb showed itself; so that for a whole winter it remained extremely cold, and ever since, for twenty years, its temperature has been lower than that of the other leg. Swan[2] has also observed a case of permanent reflex contracture of bloodvessels. I will revert to this subject in speaking of reflex muscular atrophy.

Paralysis.—I will not enter here into the discussion of the great question of the mode of production of paralysis when caused by an irritation of a nerve. I will only say that there are two absolutely different kinds of paralysis produced by such an irritation: in one kind a congestion or even an inflammation takes place in a part of the nervous centres by an influence exerted by the peripheric irritation, and the paralysis then produced is accompanied by the usual symptoms of congestion or inflammation of some part of the brain or spinal cord; while in another kind the paralysis exists without any symptom of congestion or inflammation of the nervous centres. This second kind of paralysis caused by an irritation of a nerve is most likely due, at least in some cases, to a reflex contracture of bloodvessels[3] in a part of the nervous centres. In some cases, if not in all, it may also depend, however, on a peculiar influence exerted on nerve-cells, in these centres, by an irritation starting from peripheric nerve-fibres, producing what has been called *inhibition*, or, at any rate, changing the condition of activity of these nerve-cells.

[3] An able physician, trying to ascertain

Paralysis of the various muscles of the eye, including the iris, is pretty often observed in cases of wound of the infra- or supraorbital nerves, or in cases of neuralgia. I have seen several cases of that kind of paralysis (caused by a neuralgia), and all characterized by their evident relations with that cause.

In a case which I have carefully watched, a sprain of *one arm* at the elbow-joint soon produced a paralysis of *both arms*, but more marked in the uninjured arm than in the other. Every change in the degree of pain in the injured elbow was accompanied by a corresponding change in the degree of the paralysis. The pain has now ceased for many years, and the paralysis, which ceased with it, has not reappeared, the two arms having at present as great power as they ever had before the injury.

Baron Larrey states that almost all the men who received slight wounds of the shoulder in the Syrian campaign were attacked with paralysis of the injured limb. These patients were cured in Egypt, where the air is purer than in Syria. In some, at least, of these cases, the paralysis was clearly due to an influence exerted on the nervous centres by the irritation of superficial nerves.[1]

Facial paralysis from a neuralgia is not rare; in one case this paralysis and neuralgia were both caused by the irritation of the infra-orbital nerve, and cured by the extirpation of the irritating cause, a piece of porcelain.—(Jeffreys, quoted by Tillaux, Des Affections chirurg. des Nerfs, p. 15; Paris, 1866.) Fabricius Hildanus, quoted by J. Barthez (loc. cit., p. 83, vol. ii.), relates a case of paralysis of one arm, caused by a piece of glass in the ear.—The arm may be paralyzed by an influence arising from very distant nerves. Drs. S. W. Mitchell, Morehouse, and Keen[1] give two interesting cases, in one of which the irritated nerve was the sciatic, and in the other the crural.

Parsons mentions a case of paralysis of the face and arm, caused by a prick.[2]

Roche, in an able dissertation, relates the case of a physician in whom general convulsions and afterwards complete paralysis of sensibility and motion in the left arm appeared, after the painful extraction of two teeth of the left upper jaw. There was also loss of speech, but no alteration of intelligence. In an hour the paralysis disappeared, and speech returned.[3]

As regards the lower limbs, I will simply refer to my work On Paralysis of the Lower Extremities, in which a number of facts show that a peripheric irritation of nerves may produce that form of loss of movement.

I will only say here that one of the lower limbs may be alone paralyzed, as in a case by A. Boyer, in which an irritation from a dislocated elbow was (according to all appearances) the cause of paralysis of the corresponding lower extremity.[4]

Cases of more extensive paralysis are also reported by the three American authors I have named. Schenkius (Barthez, loc. cit., vol. ii., Notes, p. 41), has seen a case of general paralysis produced by a wound of the eyebrow.—I have been consulted by an American officer who became paralyzed in a slight degree in the four limbs, chiefly the right arm and the left leg, from a gunshot wound of the cervical plexus, and partly also of the brachial plexus of the right side.

I have seen a most interesting case of general paralysis, caused by an irritation of the nerves of the penis, cured by the successful treatment of balanitis and the operation for phimosis.

Hemiplegia from peripheric irritation is less frequent than partial paralysis or paraplegia.

There are, however, some remarkable cases on record. In one of them, published by Dr. Shearman, there was hemiplegia of the right limbs, caused by tic douloureux of the right inferior axillary nerve. Tonics and galvanism cured the patient.[5]—In another case, recorded by Baron Larrey, a lady was attacked with hemiplegia on the same side where she suffered from a facial neuralgia,

---

the correctness of a statement of mine, that an irritation of nerves of the kidney may, by a reflex action, produce a contraction of bloodvessels of the pia mater of the spinal cord, has been unable to succeed, owing to the fact that after having laid bare that nervous centre, he vainly looked for bloodvessels on the surface he had under his eyes. Had he waited some time, he would not only have seen bloodvessels appear where he at first had not seen any, but he might have had the proof that there is a contraction of the bloodvessels of the surface of the spinal cord, powerful enough to render them almost invisible, and occurring when the incito-motor nerves of the skin and other parts of the back are strongly irritated in the operation of laying bare the cord.

e hemiplegia being more evident during e attacks of neuralgia; both affections were red by moxas.[1]

I have collected thirty-seven cases in which here was hemiplegia, due to an irritation of ither the auditory or the trigeminal nerves ear their origin, or of the crus cerebelli. I ave tried to show elsewhere that, in those ases, the paralysis which exists in the limbs on the side of the irritated part, is probably due to a reflex influence.[2]

Sir Astley Cooper mentions the following fact: "Mr. Toulmin attended a lady on account of her suffering severely from a diseased tooth, and she appeared also to be afflicted with hemiplegia. Mr. Toulmin extracted the tooth, and in a short time the paralytic affection entirely subsided.[3]

Anæsthesia.—A reflex anæsthesia is not rare in cases of neuralgia.

Many cases of reflected anæsthesia from a wound and other injuries of nerves are on record. A remarkable case of Baron Larrey (*loc. cit.*, vol. v., p. 35, 1821), and an important one of Roche (quoted in my Lect. on the Centr. Nerv. Syst., p. 131), particularly deserve to be mentioned. I have observed anæsthesia of the arms in an able lawyer of London, which was caused by a blow on the back of one knee. Several interesting cases have been published by Drs. S. W. Mitchell, Morehouse, and Keen. In one case a shell-wound of the left thigh produced anæsthesia of the right thigh.[4] I have several times seen anæsthesia of the whole of one side of the face, in cases of neuralgia of one part of the trigeminal nerve on the same side. I have seen also a case of anæsthesia of a part of the forehead and face, in consequence of the irritation of a branch of the fifth pair, on the cheek-bone, by a bruise. In those cases the anæsthesia subsided when its cause was cured.

Amaurosis.—The cases of amaurosis due to an irritation of the trigeminal nerve are frequent enough for my dispensing with quotations of cases. In the first edition of this work I had quoted cases of Wardrop,[5] Notta,[6] Dr. Noyes, of New York,[1] and Mr. J. Hutchinson.[2] This last observer has since published several able papers on this subject. I have myself seen five or six cases of amaurosis evidently due to an irritation of the infra- or supraorbitalis nerve. Cases of amaurosis due to an injury of a nerve of the trunk or limbs are not frequent. Dr. J. B. Colhoun has reported a remarkable case of sudden and almost complete amaurosis of both eyes, caused by a gunshot wound of the scapula.[3]

Deafness. — A neuralgia of the face sometimes produces loss of hearing; other kinds of irritation of branches of the fifth pair may also cause deafness. Dentition and decayed teeth have been pointed out as having had the same effects. Pearson relates a case of wound of the thigh in which deafness was among the symptoms produced (Medical Facts, vol. vi. p. 109).

Collapse.—I only wish to say here, that my experiments on several species of animals, compared with facts observed in man, show that there are, at least, three different kinds of collapse: the first, one in which a reflex arrest or diminution of the heart's action predominates; the second especially characterized by a great diminution of breathing, produced by a peculiar inhibitory influence on the central organs of respiration, the heart continuing to beat with more or less vigor; the third, which I have recently described in my lectures at the Faculty of Medicine of Paris, consisting in a powerful influence exerted by a peripheric irritation on the nervous centres of the nerves able to act on circulation, secretion, and nutrition, and, through that influence, producing a cessation of some of the ordinary interchanges between the blood and the tissues. Two opposite conditions of the bloodvessels may exist in this third form of collapse; these contractile tubes may be dilated or contracted. But in one or the other of these conditions, the blood, instead of being black, in the veins, is reddish and sometimes arterial-looking, and the production of heat ceases in the capillaries. This third form of collapse, consisting, as I have said, in a cessation of the ordinary chemical interchanges between the tissues and the blood, is the most prominent in a large number of cases, and it is also the most dangerous of the kinds of shock or collapse.[4]

Loss of smell, taste, and hearing.—The celebrated experiment of Magendie, showing that a section of the trigeminal nerve may cause a loss of the five senses in the head, is, most likely, to be explained by a reflex influence. At any rate, an important case of Dr. Blondlot shows that an irritation of the infraorbitalis nerve (wounded) may produce, by a reflex action, loss of hearing, taste and smell.[1]

[1] Recueil de Mémoires de Chirurgie, vol. v., 1821.

[2] Lect. on the Physiology and Pathology of the Central Nervous System, pp. 201, 264.

[3] Lect. on the Principles and Practice of Surgery, vol. i., p. 6, 1824. Dr. Castle, of New York, mentions a case of paraplegia caused by decayed teeth, quickly cured by the extirpation of these teeth (Lancet, 1846, vol. ii., p. 267).

[4] See an excellent paper by Dr. S. Weir Mitchell, on "Paralysis from Peripheral Origin," reprinted from the New York Medical Journal, 1866, p. 59. I have lately found that the irritation of the sciatic nerve in the lower animals produces a slight anæsthesia of the lower limb on the opposite side, and of the face and neck on the side of the irritation.

[4] See my article on "Syncope," in Archives de Physiol. normale et pathol., 1869, p. 767.

Neuralgia.—The frequency of *tic douloureux*, caused by an irritation of a small part of the dental nerves, is such, that it is certainly useless to mention cases. But tic douloureux may be caused by irritations of other nerves, while also an irritation of the nerves of the jaw may cause a neuralgia elsewhere than in the face. Mr. Harvey has seen a case of tic douloureux caused by a tumor of the head. It was ascertained several times, that pressure on the tumor brought on a severe attack of tic. The patient was cured by the removal of the tumor.[2]

In the first edition of this work, I gave cases of reflex neuralgia reported by Mr. Gay,[3] Dr. R. Rowland,[4] Parsons,[5] Tavignot,[6] Dr. Greene, of New York,[7] Wardrop,[8] Maréchal,[9] Dr. Castle, of New York,[10] Marchal de Calvi,[11] and Romberg.[12] The view I then maintained, that a neuralgia may be caused by a reflex action, being now pretty generally admitted, I only give here a reference to these cases, and to important publications made on this subject by Ch. Londe,[13] J. Mason Warren,[14] and Ch. Mauriac.[15]

Delirium.—I will simply mention here three cases which show quite decisively that delirium may be caused by an injury to a nerve.

A boy, aged fourteen, trod on a piece of glass, which penetrated the big toe, but was removed. Four years after, he began suddenly to talk in a very strange, wild way; true delirium set in, and nothing appeased the patient. Near the ball of the big toe a small reddish elevation was found. The moment pressure was made upon it, the seizure returned with violence. An incision was made and a trifling piece of glass was removed. Much as the patient had raved during the operation, with equal suddenness did all the symptoms vanish; and he was surprised on being told of all the senseless things he had uttered.[1]

I have published a case very similar to this, which I owe to the kindness of Mr. Campbell de Morgan, and in which the attacks of delirium took place every time pressure was made on a wound of a toe containing a foreign body. As soon as the irritated part was taken away by the cut of a bit of skin, the patient became rational, and remained so when pressure was made on the wound.[2]

Mr. Sherwin has seen a woman, who, after having been bled, was attacked with pains in the arm, neck, and face, with spasms in those parts, and delirium. After the symptoms had continued a fortnight, a deep incision above the cicatrix quite cured her.[3]

I need not speak here of the delirium that follows amputation or other great operations. The causes are many that bring on delirium in such cases. Among the principal causes I will point out a great loss of blood, and the anxiety of the patient.

Aphasia.—An interesting case shows that this affection also can be produced by an irritation of a nerve. Dr. Guyot has seen aphasia occurring every time an attack of facial neuralgia took place; the patient was cured by quinine.[4]

Inflammation.—Cases of inflammation of the eye due to a reflex action are so frequently met with, that I need not stop here to prove their existence. Any one who will read the facts published by Dr. W. Mackenzie, in his admirable work on the Diseases of the Eye, by Mr. R. Taylor,[5] by Dr. Brondeau,[6] and by several other more recent writers, among whom I will only quote Dr. J. J. Maats,[7] a pupil of Prof. Donders, will soon be convinced that an inflammation of any part of one eye (the retina, the cornea, the conjunctiva, etc.) may be caused by a wound or an inflammation of the other eye; and that if the first diseased organ is extirpated, the other is often soon cured. Cases of ophthalmia owing to a wound or a neuralgia of the infra- or supraorbital nerves, or caused by an irritation of the dental nerves, are also not rare. Dr. Busschaert has published a curious case of ophthalmia produced by obstruction of the external auditory canal.[1]

Dr. Rowland relates several facts which seem to prove that an inflammation in one side of the brain may be caused by an injury to a nerve in the other side of the body.[2] To the cases of inflammation of the brain mentioned by Dr. Rowland, I might add several others, among which the most significant have been recorded by Hennen,[3] R. Bright,[4] and Champsaur.[5] The well-known fact that sometimes, in traumatic tetanus, the spinal cord becomes inflamed, shows that a peripheric irritation may produce inflammation in that organ.

Inflammation of the testicle is also sometimes produced by a reflex action from an irritated nerve, as in cases by Sir Benjamin Brodie,[6] Barras,[7] Marrotte,[8] and others. Sir Astley Cooper[9] says that by irritation morbid actions are excited in distant organs, and adds: "thus inflammation is produced in the testicle from irritation in the urethra."

Inflammation of the abdominal or thoracic viscera may also be produced by a reflex action. Proofs of this assertion are abundantly furnished in Lecture X. of my work On the Central Nervous System. A reflex inflammation may be brought on to such a degree as to cause an ulcer, which nothing can heal until the cause (viz., the irritation of a nerve) is removed. Sir Astley Cooper mentions several cases of that kind.[10]

As well shown by Mr. J. Hamilton, there is sometimes in cases of wounds of nerves a deceptive appearance of inflammation with suppuration.[1]

Coma.—This most dangerous morbid state may also be caused by a peripheric nervous irritation.

In a case of Hirsch, quoted by Dieffenbach,[2] convulsions and coma accompanied local neuralgia, caused by venesection. The patient was cured by two deep incisions over the wound.—An immediate cure of coma and convulsions was also obtained in a case similar to the preceding, observed by Dr. Wilson.[3] Another case somewhat similar, has been recorded by Mr. G. Bell.[4]

Apoplexy. — Even apoplexy can be caused by a peripheric irritation.

A remarkable case of wound having caused neuralgia and apoplectic attacks has been observed by Dr. Maupin.[5] Other cases are mentioned in my old journal.[6]

Muscular atrophy.—I have seen a number of cases of atrophy of muscles produced by a reflex influence from an irritated nerve.

In one case *all the muscles of the thumb* wasted very rapidly after a deep wound of the ulnar side of the forearm having divided the ulnar nerve. This cannot be explained by the fact that that nerve sends a branch to two muscles of the thumb, as not only these two muscles, but others, and especially the abductor and the opponens, were notably atrophied.

A neuralgia very often produces atrophy in neighboring muscles. My friend and pupil, Dr. Cl. Bonnefin,[7] has seen nineteen cases of muscular atrophy caused by a neuralgia. A remarkable fact, observed in those cases, serves to explain how the atrophy was produced—there was a marked diminution of temperature, most likely due to a spasm of bloodvessels. The amount of blood was

A long list of authors having spoken of muscular atrophy caused by sciatica, is given by Dr. Lagrelette, in his exhaustive work on that kind of neuralgia, entitled Étude histor. séméiolog. et thérapeut. de la Sciatique, pp. 34–35. Paris, 1869. See also Notta's paper in Archives de Médecine, sept., 1854, p. 557.

consequently diminished, and the wasting occurred owing to the lack of nutritive fluid. Some of the cases of wasting palsy related in Dr. Roberts's excellent work,[1] very likely belong to the class of reflex atrophy.

In a case recorded by Vallez, a wound of the infra-orbital nerve produced a reflex atrophy and paralysis of the face on the same side.[2]

Atrophy of the cellular tissue.—In some of the cases of atrophy of one side of the face, which Schott and Romberg have called facial trophoneurose, there was an irritation of some sensitive nerve, probably acting by a reflex influence. I saw a case of that rare affection, three years ago, in Boston (United States); its probable cause was an irritation of the dental nerves, which produced convulsions in one side of the face (the side where the atrophy was afterwards observed). I will refer for arguments leading to the conclusion that the cellular tissue is alone atrophied in that affection, to a remarkable essay by Dr. L. Lande.[3]

Hypertrophy.—Notta mentions cases of hypertrophy of the face and tongue caused by neuralgia.[4] I have seen a case of considerable hypertrophy of the bones and of the cellular tissue, in the face, which occurred after repeated attacks of neuralgia, in a lady whose general health was excellent.

Various kinds of alterations of nutrition and secretion.—The number of facts that might come under this head has considerably increased since the time that my friend, Sir James Paget,[5] first showed how great may be the direct and the reflex influences of the nervous system in disturbing nutrition. *Eruptions* of various kinds (*erythema*, *pemphigus*, *urticaria*, *acne*, and especially the different forms of *herpes*) are often produced by a reflex influence from an irrritated nerve, as proved by facts observed by Rayer, G. Simon, Delioux, Notta, Romberg, Hasse, Parrot, and more recently by Charcot, Barensprung, J. Hutchinson, H. F. Damon, Purdon, and others. I have seen several cases proving clearly the production of certain eruptions by a reflex action. Sir Astley Cooper relates a curious case of *fungoid granulations protruding through an ulcer* in the cheek of a lady, who was quickly cured after the extraction of a tooth.[1] In a case of *ulcerations* and wasting, probably due to neuralgia, Dr. Hooker cured the patient by dividing the popliteal nerve.[2] An *erysipelatous redness* and swelling has been seen by Sherwin in a case of wound of a nerve, and a *swelling* of the foot and leg has been observed by Dr. Watson, of New York, in a case of cut of the sole of the foot by a piece of glass.[3] *Œdema* is a frequent reflex effect of neuralgia. Hamilton has seen two cases of that serous effusion after injuries of nerves.[4] Those persons who know that even *gangrene* may be caused by an influence of the nervous system, as rendered so probable by Dr. M. Raynaud,[5] will not be reluctant to admit that it may be the result of a reflex influence from irritated nerves. Most likely it was not to embolism or to thrombosis, but also to a reflected nervous influence, that gangrene was due in three cases related by Sir William Fergusson,[6] Dr. Gubler,[7] and Dr. Grainger Stewart.[7] The case of Dr. Stewart is especially worthy of attention. *Altered secretions* are very often due to a reflex influence in cases of neuralgia, and sometimes in cases of wounds of nerves. *Diabetes* is most likely produced by a reflex influence when it comes after a peripheric injury. It may be objected, however, that concussion of the brain is then its constant cause. I have not room enough to discuss the question here, but I think that the possibility of a reflex origin to mellituria is clearly established by cases like those reported by Dr. W. R. Hill, in which a burn was the cause of the secretion of sugar.[9] Cases of alteration of hair due to neuralgia or injuries of nerves are not rare, and I could easily mention many, showing changes in color, in thickness, in abundance, and in rapidity of growth of hair.[10] *Cataract and glaucoma* have been pointed out also as evidently resulting, in some cases, from an irritation of nerves.[1]

[10] I found lately that in some animals the division of the sciatic nerve is almost always followed, in two or three months, by a fall of hair in the neck on the side of the lesion.

SECTION II.—GENERAL FEATURES AND RULES OF TREATMENT OF THE VARIOUS AFFECTIONS CAUSED BY AN IRRITATION OF A NERVE.

The following features usually characterize cases of neuralgia, paralysis, epilepsy, and other affections brought on by a peculiar influence, exerted upon, or through a nervous centre, by an irritation of a nerve.

1st. Previous to the appearance of a remote affection due to such an irritation, the patient has suffered for a variable time from a neuralgia or a neuritis, from a wound or a burn, or from pressure upon a nerve, by either a tumor, a displaced bone, or a foreign body.

2d. An increase or a decrease of the irritation of a nerve is often followed by corresponding changes in the intensity of the remote affections caused by the peripheric nervous irritation.

3d. The various modes of treatment of nervous and other affections, produced by an influence exerted on the nervous centres by a peripheric irritation, are generally quite unsuccessful so long as this irritation persists unabated.

4th. The various affections produced by a peripheric nervous irritation are frequently cured or relieved at once, or very soon after the removal of their cause, viz., the irritation.

I may add a few other characters, more or less implied, however, in the preceding: 1st. When remote affections due to a peripheric nervous irritation occur by fits, it is not rare to see the fit suddenly produced (completely or incompletely) when the diseased nerve is irritated by pressure, or otherwise (application of galvanism, for instance). 2d. Narcotics, applied to the diseased nerve, will very frequently diminish, at least for a time, the remote affection, even, sometimes, when it consists in, or is connected with, a notable alteration of nutrition.

The above characters may all serve for the diagnosis of remote affections caused by a peripheric nervous irritation; but the only essential one consists, of course, in the pre-existence of a lesion of a nerve. It must be remembered, that if the trunk of a nerve is inflamed, all the symptoms spontaneously mentioned by the patient may seem to him to exist only at the terminal ramifications of that nerve. There is but one way to ascertain what the starting-point of these symptoms is: it consists in the examination, by pressure, of as much as possible of the whole length of the nerve, from the periphery to the neighborhood of the brain or spinal cord. Had this rule been applied in the following case, it would not have been published and accepted as a case of reflected influence from a disease of the nerves of the thumb upon the four limbs.

> Lady —— was attacked suddenly by an acute pain, soon followed by redness and swelling in the left thumb; and the other fingers gradually were also attacked, and afterwards the forearm. There was contracture and paralysis, with hyperæsthesia. The other arm became affected in a similar way; and when the pain was violent, there was paraplegia. No benefit was obtained from powerful narcotic applications on the left thumb and hand; but the patient was cured after the use of a counter-irritant ointment rubbed over the arm.[1] In this case there had been no injury to the hand; there was no neuralgia; and the symptoms observed in the fingers and the forearm were those we find in cases of local meningitis, or inflammation of the sheath of nerves, at their exit from the spine. I have seen five similar cases, four of which were cured by counter-irritants applied to the spine.

The wonderfully powerful and varied influence exerted by an irritation of a nerve is not due to pain, but to an action of peculiar incident non-sensitive nerve-fibres, as is well proved by two sets of facts: first, that there may be no pain, and even no sensation of any kind, in certain cases in which, however, a peripheric nervous irritation causes a neurose,[2] or another affection, as, for instance, in cases of worms in the bowels; secondly, that we every day see cases of pain from neuralgia, or other diseases of nerves, without the production of any remote affection. In only few cases seen by myself or others, was there such an agonizing pain as in a patient, in whom a ball had lodged in the trunk of the radial nerve, producing for many days the most excruciating pain, depriving him of sleep, and causing a continued perspiration from his face, without any other marked reflex action than a contraction of the forearm upon the arm.[3]

[3] Case of Denmark, in Med.-Chir. Trans.,

It may seem quite surprising, and perhaps incredible, that the same cause, viz., an irritation of a nerve, will either produce no effect at all, or produce such a variety of affections as I attribute to such a cause. But those who will take the trouble of studying the variety of effects of a clear cause of reflex action, such as, for instance, the exposure of many people to a cold wind when they come out perspiring from a very warm room, will understand that reflex effects may be exceedingly various, although resulting from the same peripheric cause.

Treatment.—Of the various means of treatment of the reflex and other remote effects of the irritation of a nerve, the most important may be classed into two groups—the local and the general means. As regards the local means, they consist chiefly in applications of revulsives or sedatives, or in an amputation, or division of a nerve; while the general means consist chiefly in the use of remedies that will diminish the reflex power, or the morbid excitability of the irritated nerve.

Local means of treatment.—Of these means, the best theoretically are also the best practically, according to the mass of facts I have collected. The section of the injured or irritated nerve between the brain or spinal cord and the part of the nerve which is altered, is certainly the most important local means. I hardly need to say, that if this operation is to be performed, the sooner the better, in cases of hydrophobia, epilepsy, tetanus, reflex neuralgia, paralysis, etc. Of course, if there is any reason to fear that the irritating cause will persist after the time necessary for the reunion of the parts of the divided nerve, an excision of an inch or two, which will retard reunion, must be made instead of a simple division. There is no doubt that in a number of cases (especially those of long duration) this operation will not succeed; and there are many discouraging facts, showing that the alteration of nutrition produced at a remote distance from the irritated nerve will continue after the division of the nerve, owing to causes yet undiscovered, or to an inflammation of the nerve in a great length between the place of the section and the nervous centres. It would be prudent always to excise at least a very small part of the length of the nerve, to ascertain, by a microscopical examination, if it is inflamed at the place of the operation; as, if such be the case, another division ought to be performed much higher up, and even as near the nervous centre as safely possible. In a paper recently published by M. Arloing and M. Tripier,[1] they give good reasons for the division of all the nerves of a limb in cases of tetanus; but I do not think that this radical proceeding is essential in a large proportion of cases of tetanus.[2] Still less would it be essential in most other affections due to the peripheric irritation.

There are cases in which, instead of dividing a nerve, all that is necessary is to gain a few days to allow a wound to heal up. I proposed, several years ago, to make use, in those cases, of a simple means, consisting in laying bare the nerve above the wound, and in dropping sulphuric ether upon it. This operation, especially if ether is often applied, may render the nerve, for many days, quite unable to transmit any irritation from the original wound.

Amputation of a limb should never be resorted to with the view of curing reflex epilepsy, tetanus, etc., unless, of course, this operation happens to be necessary for another purpose.

In hydrophobia, besides the section of the nerve at a notable distance from the wound, it would be prudent, after a double section, to withdraw the whole length of the nerve from the place of the upper section to the place of the lower one, which should be near or below the original wound (*i. e.*, the bitten part).

Subcutaneous injections of narcotics just above the wound, or on the irritated nerve, together with applications of emollient and narcotic lotions, or poultices, on the wound itself, are among the best local means for neurotomy. I have sometimes obtained the cure of chorea, of irregular attacks of convulsions, of *reflected* neuralgia, and even twice of epilepsy, by subcutaneous injections of narcotics (from half to two-thirds of a grain of morphia, together with from one-sixtieth to one-twenty-fifth of a grain of atropine.)

I have derived some benefit also in cases of epilepsy with a distinct peripheric aura, from applications of temporary circular blisters, like a ring, around a limb or a finger.

Applications of ice, or even sometimes of a freezing mixture, on the spot where a nerve is wounded or irritated, might be sufficient to produce a cessation of its influence on the nervous centre or another

1813, vol. iv., p. 48. The patient was cured by the amputation of the arm.

[1] Archives de Physiol. normale et pathol., p. 245, 1870.

[2] While correcting the proof of this article I received a number of the Boston Medical and Surgical Journal (March 31, 1870, p. 238), in which I find a case of severe traumatic tetanus, cured by exsection of the internal plantar nerve. Dr. G. E. Foster, who reports the case, states that "no spasm of any kind" occurred after the operation.

organ. Induction of local anæsthesia by applications of ether spray just upon and above the wound might also be employed with benefit. Before dividing a large nerve, or several nerves, one of these means should be tried.

The actual cautery, applied at white heat, may also be extremely useful. It is perhaps the best, and one of the least painful counter-irritant means.

I need not say that foreign bodies, tumors (neuromatous and others), or vicious cicatrices, etc., giving rise to reflex affections, should be extirpated.

General means of treatment.—After anæsthetics, the most powerful agents to subdue the reflex excitability of the nervous centres are the bromides of potassium and ammonium, belladonna, Indian hemp, aconite, hyoscyamine, ergot of rye, and turpentine; to which list now a few other substances, such as the chloride of barium, Calabar bean, and chloral can be added. It ought to be remembered that in many cases of reflex affections, the most powerful narcotics, especially opium, and also other remedies, such, for instance, as the chloride of barium, may be borne in very large doses without any poisonous effect. It would be impossible to say more as regards the general treatment without entering into details which I have not room enough to give,[1] and also because the rules must vary considerably according to the kind of reflex affection to be treated, and the special features of each case.

LOCOMOTOR ATAXY.

By J. Lockhart Clarke, M.D.

Revised by Roberts Bartholow, M.D., LL.D.,

Although locomotor ataxy comes more frequently under the care of the physician than the surgeon, yet in the early part of its course the symptoms are so equivocal, and so liable to be mistaken for those which belong to certain surgical diseases, that for the sake of the differential diagnosis alone, a short description of this malady should have a place in every system of surgery.

Among its chief peculiarities are the progressive development of the most prominent symptoms at intervals of considerable length; the irregularity with which, in the order of time, some of these symptoms make their appearance in different cases, and consequently, the different way in which they are grouped together. It is to these circumstances that we must attribute, in a great measure, the difficulty which frequently attends the differential diagnosis of this disease.

The symptoms observed in different cases on record are the following:—Strabismus, diplopia, amblyopia, amaurosis, ptosis, contraction of both pupils or only of one; shifting pains in different parts of the body, chiefly in the extremities; cutaneous and muscular anæsthesia and loss of sense of temperature; ataxy, or inco-ordination of voluntary movements; incontinence of urine and dysuria; loss of electro-muscular contractility in a greater or less degree; occasionally, but rarely, some paralysis of the first, fifth, seventh, eighth and ninth cerebral nerves; spermatorrhœa, with loss of sexual power and desire; œdematous swelling of the joints, chiefly of the knees; cardiac and gastric disturbance.

All these symptoms are never associated together in any one case of locomotor ataxy; and, as already stated, the variety of ways in which they are grouped constitutes one of the peculiarities of the disease. Thus, to give a few practical examples, the symptoms are grouped in the following way, and made their appearance in the order of time in which they are mentioned.

Case I. Strabismus and diplopia; pains in the legs, with numbness of toes; ataxy or unsteadiness of gait; numbness of fingers, followed by pains in the arms and unsteadiness of voluntary movements, or ataxy; incontinence of urine.

Case II. Great nervousness and external strabismus of right eye, weakness of both legs and of right arm; numbness in dorsum of each foot, in right hand as high as the wrist, and in joints of little and ring-fingers of the left hand; slight numbness round the mouth; pains in upper and lower extremities, and in head: ataxy; incontinence of urine and dysuria; some impairment of smell and taste; rachialgia, and griping in the bowels; loss of sexual power and desire.

---

[1] I will refer for details to my work On the Diagnosis and Treatment of Functional Nervous Affections, the first part of which, treating chiefly of general therapeutics, was published in 1868.

Case III. Pains, with numbness and heaviness of legs; pains in abdomen and chest; ataxy; pains and numbness in hands and arms, followed by ataxy; analgesia; incontinence of urine and dysuria, alternately; hemorrhoids; loss of sexual power.

Case IV. Hemorrhoids, with pain and numbness in sacrum and perineum; heavy forcing pains in rectum, with tightness and weight in abdomen. Subsequently pains in legs. Both pupils contracted to size of pin's head; ataxy of movement; loss of taste and smell; impaired sensation and motion on right side of nose; great numbness of feet and legs, and analgesia; numbness of fingers; "quivering" of muscles; exalted reflex excitability of skin over feet and legs.

In many cases the pains in the limbs are for an indefinite, but sometimes for a very long period the only precursors of the other symptoms with which they are subsequently associated. They consist of two kinds—the one more or less dull, aching or gnawing, and frequently described by the patient as rheumatic; the other more acute and lancinating, like electric shocks. The former are more continuous; the latter occur suddenly, in paroxysms which last from a few hours to a few days, and as suddenly disappear for an indefinite period. Even during the paroxysm the pain is not continuous, but intermitting, although it may recur in rapid succession at very short intervals, and may either fix on some particular spot, or fly from one part to another with the rapidity of lightning. The parts which most frequently suffer are the lower and then the upper extremities. [Besides these pains some patients suffer from girdle pains. The limb feels as if embraced in a cuirass, or as if a garter were firmly tied around the leg. The band-like sensation around the body at the waist, so common in spinal diseases, is usually present in this affection. Sometimes an intense burning pain is experienced in spots, which afterwards exhibit trophic changes — become discolored, or smooth and glossy, or the epidermis exfoliates.

Anæsthetic spots and areas are sometimes affected by exquisite pain: a pin may be thrust into such spots without exciting any sensation, and yet the most intense pain may occur paroxysmally in them. The pains of this disease are much affected by atmospheric changes, are worse in winter, in damp and cold weather, and are improved by warmth and dryness, by the summer temperature; hence, the apparently rheumatic character of the pains, before other symptoms arise.]
